2. The Rôle of Carbohydrates in the Treatment of Toxemias of Early Pregnancy.—Titus, Hoffman and Givens discuss theories regarding the etiology of toxemia of early pregnancy, the development of treatment from a dietetic standpoint, giving in tabular form a general outline for diet high in carbohydrates, and the application of the carbohydrate deficiency theory; review their cases under three groups, and give a pre-

liminary report of chemical and experimental investigations. Their views are set forth in the following conclusions: 1. The problematic relationship between mild and profound toxemias of pregnancy warrants a study of the former in order to gain information regarding the latter. 2. The development of a course of treatment, the success of which seemed to depend on the use of carbohydrates in large amounts, led to the assumption that a deficiency in carbohydrates has an important bearing on the origin of toxemia of pregnancy. 3. Carbohydrate deficiency during pregnancy is of twofold origin: (1) a relative deficiency due to an unexpected demand for glycogen on the part of the fetus and the uterus, and (2) an actual deficiency, augmented in the presence of nausea and vomiting, from lessened carbohydrate intake. 4. Carbohydrate deficiency in the maternal organism causes a glycogen depletion of the liver, because this is the organ in which carbohydrates are stored for use as needed. 5. There is experimental evidence to show that liver function is impaired and the body flooded with toxins after carbohydrate starvation. 6. Pathologic changes in the liver lobules which are similar to those of fatal toxemias of pregnancy can be produced experimentally by the use of certain chemical poisons. These changes can be made to disappear rapidly by the ingestion of carbohydrates. 7. Mild cases of nausea and vomiting may be controlled by so regulating the diet that there is a preponderance of carbohydrates, and an avoidance of more than short intervals of fasting by the taking of food more frequently than under ordinary circumstances. This increased carbohydrate intake should be augmented by giving the patient from 8 to 16 ounces of 10 per cent. glucose and 2 per cent. sodium bicarbonate solution daily by mouth. This may be given in 1 or 2 ounce doses. More severe cases require more rigid attention. After an initial period of rest, gastric lavage and the introduction of saline cathartics through the stomach tube, small amounts of liquid food are allowed alternately with from 1 to 2 ounces of the glucose and soda solution, every two hours. By mouth or by bowel it should be possible to give the patient 1 quart of this solution daily. In the seriously toxic patients the treatment is pushed even more vigorously with the addition of intravenous injection of from 15 to 25 gm. of glucose in from 250 to 300 c.c. of water. This is given from one to three or more times daily, according to the needs and response of the patient. 8. Not only is intravenous injection of glucose solution a valuable therapeutic measure, but the rate of its absorption and storage by the liver is an index of liver efficiency which is of prognostic value. More rapid storage than normal is favorable because it indicates that the liver, depleted as it has been of glycogen, is nevertheless still able to restore itself. Storage which is slower than normal offers an unfavorable prognosis, since this is evidence that liver efficiency is impaired.

6. Duodenal Perforation (Fistula) Treated by Duodenal (Jejunal) Alimentation.—Max Einhorn reports another case of duodenal perforation successfully treated by jejunal alimentation, report of the first cases having appeared in the MEDICAL RECORD for November 30, 1918. In the present case the diagnosis of a duodenal fistula situated between the pylorus and the papilla of Vater was established by the character of material oozing from the fistula. It was of alkaline reaction and contained food particles and usually no bile. As the patient had enough acid in his stomach the fistula must have come from the duodenum. The frequent absence of bile in it demonstrated that the opening must be situated above the papilla of Vater. This conclusion appears to find corroboration in the roentgen-ray examination and also in the clinical syndrome. The treatment consisted of atropine in conjunction with the jejunal alimentation. The patient first lost considerable weight (20 pounds). After three weeks of jejunal alimentation, the tube was pulled up to some extent so that the capsule end was now situated in the duodenum proper, thus giving real duodenal alimentation, which agreed with the patient much better, as he lost no more in weight, subsequently regaining the initial loss. The healing of the fistula by duodenal alimentation in the case described and in the one previously reported shows that in the duodenal tube and the method of feeding through it one has an important aid in overcoming this very tedious and what was formerly thought to be an almost intractable condition.

1. The Diagnosis of Glaucoma.—Lieut.-Col. R. H. Elliot considers that one of the tragedies of ophthalmic practice lies in the frequency with which one meets men and women blinded by glaucoma, simply owing to the failure of the medical men in charge to make an early diagnosis of the condition and to take unflinching action thereon. It is not that there is any real difficulty in recognizing what is wrong, but rather that the possibility of the existence of the disease is too often forgotten, with the result that the symptoms are ascribed to some more commonly met with condition. The writer approaches the subject from this angle, discussing the outstanding signs of glaucoma which first impress themselves on the attention of the patient and of his doctor, and showing the steps which the practitioner can and should take in order either to make a firm diagnosis of glaucoma or to exclude the presence of that disease. The first symptom discussed is headache, which may be a passing morning headache, headache after near work, severe headache often attended by vomiting. Loss of sight, like the headaches, may vary greatly in different patients. The typical varieties are gradual loss of sight without any apparent cause; gradual loss of sight with intermittent headaches; marked losses of sight, clearly following severe attacks of headache. With regard to the loss of vision the writer warns that when a patient thinks his sight is failing it is unwise to dismiss him as a *malade imaginaire*. It should be remembered that simple glaucoma may be far advanced, with nothing to indicate its presence but what he had ventured to call "the triad of glaucoma signs"—(a) contraction of the visual field; (b) cupping of the disc, and (c) failure of central visual acuity. Even the last named defect may be but poorly marked. Assuming the actual existence of a gradual loss of sight, the differential diagnosis must be made between chronic glaucoma and (1) cataract, (2) refraction errors, (3) brain trouble, and (4) optic atrophy. When there is gradual loss of sight with intermittent headaches one should be on the lookout for glaucoma as a possible causative factor. One should not, then, be content to treat one's patient for biliousness or for nervous breakdown until glaucoma and cerebral tumor have been considered. One should make a point of seeing the patient in an attack and then look for the dilated pupil, the rise in tension, the shallow chamber, and the evidences of ocular congestion that attend rises in intraocular pressure. In the intervals one should examine the discs and visual fields. If still in doubt, expert opinion should be sought. In cases of marked loss of sight, clearly following severe attacks of headache, the eye condition may be altogether missed unless the surgeon bears its possibility in mind.

Possible Contagion of Cancer.—Mauclaire relates the case of a man with cancer of the penis whose wife was suffering from cancer of the vagina. The former antedated the latter clinically, which fact makes the identity of the transmitter doubtful. The observation was defective, there having been no histological examination. If there was transmission there was doubt as to whether contagion or mere implantation was involved, for the two processes differ widely.—*Gazette des Hôpitaux.*

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Fourteenth Annual Meeting Held in New York City, March 23-25, 1920.

SECTION ON SURGERY.

First Day, Tuesday, March 23, 1920.

DR. CLAUDE C. LYTLE OF GENEVA IN THE CHAIR.

Remarks on the Diagnosis of Right Iliac Fossa Pains and the End Results in 200 Operations for Chronic Appendicitis.—Dr. CLARENCE A. MCWILLIAMS of New York read this paper, in which he said that their attention had been drawn to this subject because there were many individuals who continued to complain of right-sided pain after the appendix had been removed in the hope of relieving their symptoms. At the Presbyterian Hospital, during the years 1916 and 1917, 200 operations for chronic appendicitis had been performed on ward patients, who were kept under observation by a very strict follow-up system. Of these cases 145, or 73 per cent., were females and 27 per cent. were males. Cures were effected in 151, or 75 per cent.; 22, or 11 per cent., were improved, and in 13 per cent. there was a failure to cure. In this series of cases there was no instance of subsequent hernia in the scar of inguinal hernia. In a series of 58 cases in private practice, not operated on by any one man, the results were by no means as satisfactory. This indicated that hospital cases were more carefully worked up than private cases and that there should be a more careful study of private patients before operation for the purpose of detecting associated or concomitant conditions that might be causing the symptoms. It was advisable to abandon the old gridiron incision for an ample right rectus incision or a transverse incision which would allow of thorough exploration of the upper abdomen and pelvis. Dr. Charles L. Gibson had recently reported their results at the New York Hospital where during the past two years they had reduced their bad results from 30 to 11 per cent. This Dr. Gibson attributed to more thorough diagnosis, a wider incision, and the use of 5 per cent. picric acid instead of iodine which was very irritating. Many patients were operated on for appendicitis when the symptoms were caused by other conditions. Cases of splanchnoptosis were often operated on for appendicitis. Of 120 cases of nonoperated ptoses, 87 complained of right-sided pain. Hence in these cases a degree of conservatism should be exercised, unless there was a history of previous acute attacks of appendicitis. Cases of this class were as a rule greatly benefited by abdominal support. Neither Lane's kink nor Jackson's membrane were in themselves of great significance. Many of the symptoms supposed to be due to these conditions were the result of faulty posture and incorrect methods of breathing. Many adhesions in the upper abdomen and in the intestines were due to faulty posture and lack of physical development. Setting up exercises would do more for women than any other one thing. A dilated, prolapsed cecum should be plicated at the time the appendix was removed. They had had a number of cases in which this was done with benefit. The kidney and ureter might be the cause of symptoms simulating those of appendicitis. In some cases it was almost impossible to differentiate duodenal ulcer from chronic appendicitis. Chronic jejunal obstruction due to adhesions or by overlying mesenteric vessels, as well as duodenal obstruction, might also simulate chronic appendicitis. Duodenal obstruction bid fair to be discussed far more in the future than it had been in the past. It was easy of demonstration after a bismuth meal. At the time of operation for chronic appendicitis a careful exploration of the abdomen and pelvis should be made.

Dr. HAROLD BARCLAY said that undoubtedly there were too many operations for chronic appendicitis where the appendix was not at fault. Their records included some 1500 operated cases and among these there were some 100 futile appendectomies. This emphasized the importance of working up these cases more carefully before operation and of using more conservatism. As to the differential diagnosis between appendicitis and duodenal ulcer, where the *x*-ray was not available a gastric analysis was of value. Most cases of chronic appendicitis showed slight hyperacidity but by no means as much as was found in duodenal ulcer. Where a patient had all the hunger symptoms and had acidity only slightly increased chronic appendicitis or gallbladder irritation was probably present; if hyperacidity was considerably increased, duodenal ulcer might be suspected. This was so constantly true that he had come to put considerable faith in it as a differential diagnostic point. As to the cases of enteroptoses he had formerly been inclined to put them to bed and give them a so-called fattening cure, but in the last year he had to a great extent given that up; he had obtained a man who was a gymnastic instructor and had given these patients a thorough course in gymnastics, which had developed their muscles, and had them taught to breathe properly.

Dr. PARKER SYMS of New York said he thought Dr. McWilliams had expressed what was accepted as the opinion of modern surgeons on this subject, namely, that they would have to become more careful in the selection of cases for appendectomy. In a large number of enteroptotic individuals the appendix had been removed, and in many of these it was found to be abnormal, but in this class of patients the removal of the appendix would not relieve symptoms other than those due to the appendix itself. Operations for conditions supposed to be due to Jackson's membrane were usually harmful rather than beneficial. Jackson's membrane should be operated on only when there was a definite lesion as a constricting band that gave rise to symptoms. He never stripped the bowel if there were fan-shaped adhesions but divided the adhesions at the flank. The question as to the relation of iodine to adhesions should be worked out. Where iodine had been used in the abdomen for the purpose of producing adhesions in cases of tuberculous peritonitis it was found that adhesions could not be produced in this way; it might be different under other conditions. It seemed to him that adhesions were due to a certain degree of infection.

Dr. LEROY BROUN of New York said that their experience at the Woman's Hospital was quite similar to that at the Presbyterian Hospital. He thought that in operating for chronic appendicitis they should only operate on those cases giving a history of acute attacks of appendicitis. Dr. McWilliams was correct in saying that they did not study their cases carefully enough to eliminate the possibility of error. One of the best means we had of differentiating these conditions was oxygen distension of the peritoneal cavity associated with the bismuth meal and roentgenologic study. In that way adhesions could be beautifully and distinctly demonstrated if present. Dr. McWilliams was also correct in saying that many cases of ptosis were submitted to futile operations for chronic appendicitis. At the Woman's Hospital they had a severe follow-up system. A monthly report was made by the surgeon upon his cases after they had been carefully followed up and only those cases satisfactory or partially satisfactory were discussed. If a patient returned after appendectomy with a right-sided pain, that operation was put down as a failure. Such a method was an incentive to a more thorough study of the cases before operation. Frequently private patients failed to avail themselves of the methods of diagnosis that the hospitals gave to the ward patients.

Dr. JACOB KAUFMANN said the internist saw quite a number of these failures following operations for chronic appendicitis. On this question he had arrived at a number of conclusions, one of the most important of which was that it was a mistake to make anatomical findings a basis for diagnosis and to forget to study function; it was the pathological physiology that counted rather than the pathological anatomy. It had been correctly pointed out that the majority of the chronic appendicitis cases had enteroptosis, and enteroptosis was not a disease in itself but a part of a general condition which produced all sorts of abdominal disturbances. These patients were often asthenics, and were suffering from mental and emotional overtaxation which interfered with the proper function of the gastrointestinal tract, and one must take all the factors into

consideration if he expected to get satisfactory results. Removal of the appendix did not always remove the pain in the right iliac fossa because this pain originated in the nerve plexuses surrounding the arteries and often pressure on the left iliac fossa would be found to be as painful as on the right side. It was correct to remove adhesions when they produced mechanical disturbances, but one must take into consideration the make-up of the patient. He fully agreed that in the cases of ptosis it was better to give proper exercises and treatment directed to the improvement of the general tonicity.

Dr. JOHN F. CONNORS called attention to the fact that they had been taught that pain in the right iliac fossa meant appendicitis and the same thing was being taught to-day. It was true that the private patient often did not get the same careful study that was given to the ward patient. Frequently when the surgeon was consulted the family physician had already made the diagnosis and the surgeon accepted it. A great many men did the operation through the McBurney incision, and that was a small incision; that was one reason there were so many failures. The incision must be large enough to permit of a thorough exploration of the abdomen. It was important that medical students should be taught that other conditions besides appendicitis caused pain in the right iliac fossa, and they should be taught not to perform the operation through the small intramuscular incision with one finger in the abdomen.

Dr. CHARLES L. SKINNER of Port Jervis called attention to the fact that in appendicitis there was an asphyxiation of the red blood cells by the toxins from the appendix and as a result there was universally a darkening of the veins in the right iliac region as compared with those in the left iliac fossa and upper abdomen. Pain itself was of very little value from the diagnostic standpoint. One very important symptom was neuritis of the lower intercostal nerves. The finding of pain at the points where the main branches and posterior roots of these nerves were given off and pain at the terminal points of these nerves should help in differentiating intercostal neuralgia from appendicitis.

Dr. MCWILLIAMS said he did not think their results in the hospital cases were as bad as one might be led to think from the discussion. They had had practically 73 per cent. cures and 13 per cent. failures. The main point was the need of more acuteness in diagnosis. He had never been able to detect the darker color of the veins in the right iliac fossa as compared with those in the left iliac region.

Dr. PARKER SYMS asked Dr. Skinner how he thought the darker color of the veins was produced.

Dr. SKINNER replied that he could not tell exactly, though he had observed it since 1891 and had taught other surgeons to recognize it. The darker color of the veins was particularly noticeable above Poupart's ligament and in those veins that converged towards the upper part of Poupart's ligament. There was a connection between superficial epigastric veins and those of the cecum that might lead to pressure on the portal system that caused a backflow.

Surgical Physiology and Pathology of the Colon from the X-Ray Standpoint.—Dr. JAMES T. CASE of Battle Creek, Mich., gave this demonstration by invitation. He said that the slides he had to show would serve as a discussion on Dr. McWilliams paper. He first showed slides of the normal colon and described it, and then discussed the question of position versus function. The normal colon had a wide range of motion, particularly the transverse portion. Lane's kink, hepatic-colonic and other varieties of adhesions might be the cause of stasis that would eventually produce appendicitis. A cecal stasis might often be due to obstruction in the distal colon rather than to a Lane's kink or a Jackson's membrane. The colon had three types of movements: (1) The right one-half showed antiperistaltic movements; (2) the left one-half had segmental and gross movements; (3) there were propulsive movements which directed the contents from the right towards the left. The normal transverse colon assumed various positions at different times, being sometimes high and sometimes low in the abdomen. Many slides were shown demonstrating the existence of an antiperistaltic wave. Cases showing this condition were frequently cases of colitis having no surgical lesion. Antiperistaltic movements were frequently responsible for stasis in the cecum. Respiration played a great part in the physiology of the contents of the colon, and undoubtedly helped in moving them forward. Propulsive movements occurred twice as rapidly as antiperistaltic movements. A failure to understand the mechanism of antiperistaltic action might lead one to interpret an *x*-ray plate showing this action as indicating the presence of ulcer or some form of gross pathology. It was important to differentiate between a true Jackson's membrane and a loose membrane that originated from the upper surface of the liver and gallbladder which did not cause colonic stasis. It was meddlesome surgery to interfere with such a loose membrane. Adhesions of the pelvic colon were quite common after salpingectomy; these in a number of cases he had been able to relieve with very satisfactory results. Adhesions of the pelvic loop were often the cause of ileocecal pain and afforded one explanation of why appendectomy sometimes failed to relieve right-sided pain. All cases of supposed chronic appendicitis needed careful study and one should particularly study the distal colon.

Dr. L. P. VAN WINKLE of Brooklyn, speaking from the viewpoint of the roentgenologist, said that Dr. Case had certainly shown them some wonderful pathology. One of the most important things from this standpoint was a careful and painstaking examination. One could not make the diagnosis from one X-ray plate or one examination, but from many plates and many examinations, supplemented by the fluoroscope, and with the patient in various positions. He asked Dr. Case if he had been able to standardize the amount of fluid injected into the colon and whether he thought it could be standardized, since the amount of fluid injected might be an important factor in relation to the amount of distension of the colon. He also asked Dr. Case whether he resorted to the stereopticon and whether he thought it was necessar to employ pneumoperitoneum. He had not tried it. A careful examination of the right kidney and ureter was also an important point that should not be forgotten in cases of right-sided pain.

Dr. CASE, in closing, emphasized the point that the *x*-ray was not the only method of studying these cases and that in none of these cases should one depend upon the *x*-ray alone. They should be studied from the standpoint of internal medicine. As to a number of *x*-ray plates, if he were making the examination, he would not feel it necessary to make *x*-ray plates at all in some cases, because he could make the diagnosis by means of the fluoroscope, and indeed one might be widely misled by the *x*-ray unless it was checked up by the fluoroscopic examination. The stereopticon was very helpful. It was their custom to make a stereopticon examination as that showed the relation of the colon to the other parts. The amount of the enema was quite constant, being about three pints. It was allowed to flow into the colon by gravity from an elevation of about two feet. Pneumoperitoneum he considered one of the greatest advances of roentgenology to-day. It was useful in supplementing fluid in ascites; it showed retroperitoneal tumors and pancreatic cysts: it was useful in differentiating the relation of the diaphragm to the liver, kidneys and spleen, but he would hesitate to use it until he had exhausted other methods of diagnosis, though if carefully conducted it was apparently without serious danger to the patient.

Technique of Anorectal Operations Under Local Anesthesia and Rectal Instrumentation.—Dr. SAMUEL GANT gave this motion picture demonstration. He said that it was possible under local anesthesia to perform an appendectomy, a colostomy, or to do work on the sigmoid, but he did not employ local anesthesia for operations of that kind unless a patient could not take a general anesthetic. He regularly did all his rectal work under local anesthesia, using one-eighth of one per cent. eucaine. The eucaine kept indefinitely and was effective. The injections should be given intradermally. Eucaine was preferable to quinine and urea which sometimes caused sloughing an induration. In removing thrombotic hemorrhoids he simply turned out the clot and did not put in sutures. If sutures were used a drain should be employed. After removing thrombotic hemorrhoids it was a mistake to tell the patient that he would have

no further trouble. Local anesthesia was not desirable in operating on deep fistulas, or in any operation in which the surgeon did not know the extent of the operation before he started to operate. In operating for anal polyps, fissures, ulcers, or external or internal hemorrhoids, he never used any thing but local anesthesia. It was an advantage to have a large needle and a copious syringe. There was very little hemorrhage in operations performed under eucaine anesthesia. Cocaine should never be used and adrenalin was not to be recommended because it first contracted the blood vessels, and they later relaxed and secondary hemorrhage might follow. One reel showed the removal of an enormous adenoma with the patient under local anesthesia; this had necessitated keeping the patient in the hospital only over one night. He never divulsed the sphincter in cases of ulcer or fissure. Under local anesthesia a hemorrhoid operation could be performed in five minutes and a fissure operation in two minutes. In employing the clamp and cautery method in operating on hemorrhoids one was likely to have a stricture if too much skin was removed. He had seen five hundred strictures following the Whitehead operation. Dr. Gant also demonstrated his method of operating for the relief of pruritus ani under local anesthesia. He made four button-hole incisions and by scissors dissection under the skin cut off the nerves around the itching area. Hemorrhage never occurred when this form of local anesthesia was properly employed. He believed that 95 per cent. of hemorrhages following operation were due to the ether, which caused vomiting and straining. In operating for pruritus ani he gave morphine about a half hour before the operation and again about fifteen minutes after. A motion picture illustrating of his method of introducing the proctoscope and of Gant's valvotomy clamp closed the demonstration.

Dr. PARKER SYMS of New York expressed himself as averse to making injections in the neighborhood of the anus, for the reason that he objected to a stab wound in a region that could not be surgically sterilized. All one needed to do was to touch the hemorrhoids with carbolic acid and then with alcohol and then they could be opened without the slightest pain. He preferred the clamp and cautery method because he thought it was safest and most painless and gave the most comfortable convalescence. He fully agreed to the importance of avoiding a general anesthetic if possible. One could use a method of anesthesia that was not new but had been put on a scientific basis by Dr. Thompson of Nashville, that was sacral anesthesia. He had been using sacral anesthesia in all his perineal prostatectomies, and had found it universally successful. There was no danger of infection and it produced a real anesthesia.

Dr. GANT, in closing, said the results of this operation for pruritus ani were not always permanent, unless the original cause was removed. He did not get infection with eucaine anesthesia and he did not use elaborate precautions for sterilization. It took about five minutes to make the necessary preparations. He thought the secret of his success was a large operation and free drainage. Ten times he had had hemorrhages in doing the clamp and cautery operation and did not do it any longer. The application of carbolic acid and iodine had no effect on the subcutaneous tissues. As for sacral anesthesia, it took longer and one had to be very careful to insert the needle just at the right point.

Second Day—Wednesday, March 24, 1920.

DR. CLAUDE C. LYTLE OF GENEVA IN THE CHAIR.

Abdominal Incisions.—Dr. CHARLES W. HENNINGTON of Rochester presented this paper. He stated that there was still a great difference of opinion in reference to abdominal incisions. The final decision as to which was best would be decided by a further study of the normal healing of tissues. In general the location and direction of the incision ought to be determined by its effect on the muscles and innervation. The approach to this question depended upon anatomical and embryological considerations. He felt that many of the objections recently raised to the McBurney incision would vanish if attention were paid to the complete and orderly separation of the layers. Whether the high or low McBurney incision was to be employed must be determined by examination and final palpation when the patient was under the anesthetic. The low McBurney, to his mind, was preferable as it gave better access for exploring the abdomen. The occurrence of hernia after the McBurney incision was due to needless destruction of the innervation. The other lateral incision was that through Petit's triangle, with a similar spreading of the muscles. This afforded a good approach to the retroperitoneal appendix and to the kidneys and ureter. This incision also had the advantage that it admitted of excellent closure and disturbance of the innervation could be avoided with moderate care. The transverse incision had been slow in gaining favor and justly so, in his opinion. Although the transverse incision permitted of a wider exposure, the muscle fibers of the rectus muscle were longitudinal, and furthermore the transverse incision did not readily lend itself to enlargement or alteration, and the difficulties of closure outweighed those that were encountered when the muscle was divided longitudinally. The best way of closing the transverse incision was by the "cross-buck" mattress suture. The best approach to the lower abdomen was by the classical longitudinal mid-line incision. There was, of course, greater danger to the innervation from a long than from a short incision. The toxicity absorbed might be just as great from a short incision as from a long one. A wound with bruised edges, even if short, might give a greater degree of toxicity than a long one with clean unbruised edges. In closing any incision emphasis was to be laid on the exact approximation of similar structures. The explanation of painful scars was dependent upon two factors, the inclusion of nerves in the scar and traction produced by tension on the scar. He had had a special opportunity of observing scars in France, since where he was located they had a considerable number of soldiers sent back from base hospitals because of painful abdominal scars, and these men proved a serious problem. It was a question whether they could be sent back as Class A men. Many hernia operations had been done in camps in the United States, and it would be interesting to know the exact percentage of these men who were really fitted for Class A military service. He was confident that a large number of these repairs had failed to make Class A men, and he thought they should be placed in Class B limited service. The fact that many of these men who had had operations for hernia, as well as those having undergone other abdominal operations, complained of painful scars gave weight to the idea that excessive scar formation was to be avoided. In closing an abdominal wound the aim should be not merely the avoidance of hernia but actual normal anatomical and physiological restitution of the abdominal covering.

Dr. EDWARD WALLACE LEE of New York asked for an expression of opinion as to whether there was such a thing as a constitutional tendency to scar formation. He asked this because they saw a great many cases that had been cared for by the most delicate and scientific technique and yet a hard unyielding scar would form. On the other hand, there were cases receiving no attention whatever in which primary union without scar formation took place; this sometimes occurred even when there was laceration with a great deal of contusion. There was a theory that where there was keloid formation or a tendency to keloid formation there was a strain of colored blood in the veins no matter how white the person might seem to be.

Dr. C. G. GOULD of New York said he had endeavored to popularize the transverse incision in the lower part of the abdomen, but not in the upper part as he was concerned chiefly with gynecological operations. The transverse incision was being used a great deal in the Mayo Clinic. Dr. Stimson was the first man in New York to use it, but it did not become popular until Pfannenstiel developed it. It had the advantage of avoiding post-operative hernia which occurred so frequently after the median line incision. Dr. Child took issue with what had been said regarding the McBurney incision. He believed the McBurney incision was out of date. Dr. Hennington said the low McBurney incision was preferable to the high McBurney. Why not use a type of Eliot-Davis incision which fulfilled all the requirements that Dr. Hennington had laid down.

It gave a better exposure than the low McBurney incision. He was surprised that this incision had not been used to a greater extent in New York. He took for granted that non-absorbable sutures were used in closing the incision though the reader of the paper had said nothing about suture materials. As to keloids he had observed that 90 per cent. of these occurred after median line incisions. He did not think the question of race entered into the question because he had seen the same individual operated on at one time by a longitudinal incision and at another time by a transverse incision and a keloid had occurred in the longitudinal scar and not in the transverse. He did not operate on males but in females the transverse incision was the ideal one. It was in the direct line of all the tissues that they were working with and with a minimum incision a maximum amount of exposure was effected with the least amount of trauma.

Dr. E. MacD. Stanton of Schenectady said he had always felt that the question as to which was the best type of incision could only be solved by definite statistical data, by keeping clear records of early and late results for a period of one or two years following operation. He had several years ago reported five or six hundred cases before this section, and he believed the really important factor was not the question of whether a little keloid formed but whether there was really firm union. The highest percentage of hernias occurred not at three or four months but a year or so after operation, and the type of incision that caused the most trouble was the McBurney. The important point in determining firm and early union was the careful suture of the fascial layers; if this was done no matter whether there was drainage or not they would have primary healing, firm union, and no hernia. He thought it was better to drain through a point in the course of the incision rather than by a lateral stab wound. After Dr. Moschcowitz published his paper on the transverse incision in the upper abdomen in 13 cases; hernia occurred in 11 of these and he was no longer using that incision.

Dr. J. Tinkler of Buffalo said he had yet to see a hernia follow a real muscle split incision. The low transverse incision should be the incision of choice as it gave the best exposure. A real muscle split incision contracted so as to close practically without sutures. Non-absorbable material should be used to insure that the tissues were held in place until healed and one did not get firm healing in five days or a week.

Dr. Hennington said he thought the answer to this question would come through the embryologist who would make a complete study of the structure of the abdominal wall.

The Symptomatology of Perforated Duodenal Ulcer.—Dr. Robert S. Macdonald of Plattsburg presented this paper, in which he said that of all the acute abdominal catastrophies perforated duodenal ulcer was the most painful. In sub-acute and chronic perforations there was a gradual increase in the symptoms, but in acute perforation the onset was absolutely sudden. In non-perforating duodenal ulcer the symptom complex was so complete that, as Dr. Deaver said, the diagnosis could be made over the telephone. The typical duodenal case gave a history of gastric disturbance extending over a series of years. There was often a history of a feeling of fulness in the chest and eructation of gas corrected to a certain extent by alkalies. In the point of time it was important to remember that the distress occurred several hours after meals and was worse at night; food seemed to relieve the distress. There was a typical loss of weight, mostly in the spring and fall. Vomiting and hematemesis, or blood in the stools, occurred in 80 per cent. of the cases. There was gastric hyperacidity and hyperperistalsis, and often there was atoo rapid expulsion of the barium if there was no obstruction present. In many cases the time when perforation would occur could be predicted with considerable accuracy. The anatomical location of the perforation was very uncertain. At the time of perforation it was frequently impossible to tell whether it was in the stomach or duodenum. Often the right side was affected more than the left and this might lead to a mistaken diagnosis of appendicitis, gallstones, or renal colic. The site of the ulcer seemed to make no difference as to the likelihood of perforation. C. H. Mayo reported 2,113 cases of all types; in 84.9 per cent. of the perforations were duodenal and in 15.1 gastric. The statistics of the Massachusetts General Hospital showed that 69 per cent. of the perforations were duodenal, while Dr. Charles L. Gibson reported that in his cases the majority of perforations were gastric. Dr. Stanton reported 70 per cent. gastric perforations. Of his own ten cases, three were gastric, five duodenal and two were in the pyloric area. There was an interval between the early crisis and the later rigidity when it might be possible to get some idea as to the location of the perforation. He felt convinced that 70 per cent. of perforations would be found to occur in the duodenum. The greatest aid in diagnosis was afforded by a well recorded history and a series of *x*-ray findings.

Dr. Charles W. Hennington called attention to the value of methylene blue in indicating the exact location of the performation and in showing multiple perforations if such were present.

Dr. Theodore Dunham of New York called attention to early intense rigidity as a diagnostic sign in these cases. He thought if one appreciated the cause of this early rigidity he would be more apt to remember it. Perforation of the stomach or duodenum caused at first a chemical peritonitis due to chemical activity of the fluid escaping from the stomach or duodenum. The ratio of intensity of this chemical activity decreased as it went further down in the intestinal tract and the chemical gave place to a bacterial peritonitis. On the contrary, a peritonitis primary in the lower intestinal tract was bacterial. If one took an emulsion of ascitic fluid and colon bacilli and injected it, there would be no response until bacterial activity had been established, and that would be hours after the injection. In acute pancreatitis one did not get the late bacterial peritonitis because the patient did not live long enough. The position of the patien and the fixed rigidity was striking in these cases. Where perforation was present the patient wanted to keep everything away from him while in distension of a hollow viscus the patient wanted the viscus supported. One could not always differentiate this type of cases, but this condition, as well as any of those for which it might be mistaken, was such that the aseptic scalpel was indicated as the instrument of diagnosis.

Dr. John F. Connors recalled a series of 50 cases which he had reported some years ago, in 48 of which the symptoms were such that it was impossible to say whether the perforation was gastric or duodenal.

The Diagnosis of Cholecystitis and Indications for Cholecystectomy.—Dr. Alexander E. Garrow of Quebec, Canada, made this presentation. He said that a patient might give a history of cholecystitis and yet the gallbladder show little evidence of pathology either to the eye or on palpation. Often such gallbladders when opened might show a typical strawberry mucous membrane. Frequently the peritoneum in the region of the colon might show hyperemia, and there might be enlargement in one of the lymph glands in the neighborhood of the gallbladder when the gallbladder itself showed nothing definitely pathological. In fact, it might be stated that contiguous pathology offered a better criterion for the removal of the gallbladder than the appearance of the organ itself. The evidence went to show that inflammations of the gallbladder were infective in origin. They had been taught that infection was most likely to occur through the bile or from the duodenum through the common duct, but in his opinion these infections were embolic in origin. Appendicitis, ulcer of the stomach and duodenum, and cholecystitis were largely embolic infections; Rosenau had shown the selective affinity of the streptococcus for this locality. Again, the bile might be sterile and the wall of the gallbladder infected. Drainage of the gallbladder was seemingly beneficial in a considerable number of cases, but it was doubtful if such seemingly good results were due to the drainage *per se;* possibly they might be attributed to rest and the withdrawal of a small amount of bile. Drainage did not remove the major part of the bile secreted. By drainage one might secure from 90 to 100 c. c. of bile a day while the liver was supposed to secrete 500 c.c. during that

time. He agreed with those who held that cholecystectomy was the operation of choice even though there was little pathology limited to the gallbladder itself. When there was a clinical history of recurrent attacks of cholecystitis or a chronic type of inflammation it was safe to assume the presence of an infection which became active when the resistance of the body was lowered. Dr. Garrow described various types of cholecystitis and spoke of the difficulty of differentiating it from duodenal ulcer in some cases. In differentiating perforated duodenal ulcer from acute cholecystitis it might be well to remember that retraction of the abdomen was never seen except in duodenal ulcer. Fever in acute cholecystitis varied with the acuteness of the infection; chills were unusual, being rather more frequent in common duct infection; routine examination of the blood showed a leucocytosis; vomiting was not usually frequently repeated. The indication for the treatment of an acute attack of cholecystitis was drainage, provided bile was found, and so long as the bile drained away one might look for recovery, but many of these cases treated by drainage had sequelæ; hence many surgeons preferred cholecystectomy. The gallbladder was not essential to life though it might be a factor in the well-being of the individual. The symptoms of chronic cholecystitis were distressing sensation in the epigastrium; pain beneath the right scapula and over the eighth, ninth, and tenth ribs; a bad taste in the mouth in the morning and loss of appetite; some individuals were thin and others obese. Inspection of the abdomen was negative; usually there was well-marked pain on deep pressure in the gallbladder region. Examination of a test breakfast showed about normal acidity. The gastric symptoms had no direct relation to meals and usually occurred late at night. These patients were often quite comfortable for weeks between attacks. In the ordinary chronic forms of cholecystitis the gallbladder was thickened, milky white in color, and there was tenderness and rigidity; occasionally a tumor was present when the cystic duct was obstructed. Dr. Garrow reported a series of 80 cases operated on for gallbladder disease during the past two years. Of these 60 were women. The average age was 44½ years. In 45 the chief symptoms was sour stomach; 50 vomited; 27 were jaundiced; only 11 showed definite rigidity; 40 had stones in the gallbladder. A reliable follow-up was conducted which showed that 8 had recurrences of symptoms. In 44 cholecystectomy was performed. Of the eight having recurrences two followed cholecystectomy and six followed cholecystotomy and drainage. In operation he preferred the right rectus incision high up, disposing the muscle to the right, cutting the falciform ligament and exposing the gallbladder. In removing the gallbladder he began at the fundus and dissected downwards. It was of the greatest importance to secure the cystic duct quite intact from the common duct and to guard the entrance of the cystic duct into the common duct.

Dr. CHARLES L. SKINNER of Port Jervis said he thought if one kept in mind the embryology of this region he could easily see why there was such a tangle of symptoms. The liver and the bile ducts were given off from the duodenum and carried with them nerve filaments that extended to the innermost recesses of the liver and gallbladder. He thought it would be better, instead of waiting too long to make a definite diagnosis, where there had been long continued symptoms of serious disease, to make an exploratory operation.

Dr. F. W. ZIMMER of Rochester said he did not recall having heard Dr. Garrow speak of the use of the *x*-ray in diagnosing cholecystitis. It was true that barium and bismuth rarely entered the common duct, but an *x*-ray aided one in excluding ulcer of the stomach and of the duodenum. He thought it advisable to have a roentgenological examination in every case that could wait long enough for it.

Dr. G. W. COTTIS of Jamestown said the question of the apparently harmless gallbladder was most important. He has seen gallbladders that looked like a robin's egg and were causing trouble. He felt that one could safely remove a normal appearing gallbladder after excluding every other possible cause of the symptoms. There was no harm in operation and he believed this would be the next step in surgery.

Dr. E. MACD. STANTON of Schenectady said that his technique in the removal of a normal looking gallbladder had probably been bad, but he had to confess to having removed quite a number from patients whose symptoms were definitely those of cholecystitis, and in some he had found stones and a definite pathology. He had followed up these patients and found that some of them had benefited for a number of months following the operation, whether because of the rest or the psychological factor he could not say, but he knew that in a year or so they again complained of the same type of symptoms. He was rather skeptical as to the large amount of good that one might expect from the removal of the normal looking gallbladder. In his pathological experience he had found two instances of congenital absence of the gallbladder and both died of cholelangitis. It would be interesting to have the history of a series of patients who had had the gallbladder removed after the lapse of a number of years. For instance, it would be interesting to have the history and pathology of individuals at the age of 60 years who had had their gallbladders removed when they were 30.

Dr. GARROW, in closing, said he was quite satisfied that embolic infection was the explanation of cholecystitis. Frequently in cholecystitis there was an associated pancreatitis which was not recognized, and which might be responsible for the recurrence of symptoms after cholecystectomy. There were two points he wished particularly to emphasize: He did not think it made so much difference whether one dissected the gallbladder from above downward or from below upward, but it had been his experience that he could expose the parts deep down by dissecting from above. The other point was that the ligature should never be passed around the cystic duct until both the cystic and the common duct were clearly exposed and the ligature should not be placed too close to the common duct.

The Value of Position in the Operative Treatment of Hernia.—Dr. HENRY H. M. LYLE of New York gave this demonstration which was illustrated by lantern slides. He described the anatomical relationship of the abdominal and thigh muscles to Poupart's ligament and showed that when Poupart's ligament was relaxed the conjoined tnedon would be relaxed. In operating for hernia he employed a simple procedure consisting of transfixion, high ligation, and transplantation of the cord during which the patient was in the dorsal position. After putting in the first suture through the conjoined tendon, through Gimbernat's ligament and out through the lower portion of Poupart's ligament, the patient's knees were propped up with the leg in internal rotation. The shoulders were also elevated. The hinged bed that had come into use during the war was useful for this purpose. The relaxed position was maintained for seven day sand insured firm union.

Dr. GARROW referred to a method which Dr. Cunningham had used following operations for hernia which consisted in applying a long strip of adhesive plaster which passed liked a figure eight around the thigh forcing the limb up against the dressing. Cunningham claimed that this pressure prevented hematoma. Dr. Garrow said he made it a chief point in teaching students that they should take the greatest care to prevent even the slightest amount of oozing from the vessels when operating upon hernia.

Dr. LYLE said he was not presenting anything new. The same principle had been employed in the middle ages. He had simply taken advantage of a physiological principle.

Mesenteric Vascular Occlusion.—Dr. ROSS G. LOOP of Elmira read this paper, in which he said that this subject from the standpoint of prognosis and treatment had received scant attention in our literature and in the textbooks it was accorded little notice. In the French and German literature it had received much more complete discussion. Mesenteric vascular occlusion was not as rare a condition as was supposed and quite frequently it was mistaken for intestinal obstruction. He had seen seven proved cases within the past two years and was convinced that in the past he had failed to recognize many more. Its existence or non-existence in obstruction cases spelled a bad or

a good prognosis and influenced treatment. Mesenteric vascular occlusion presented two well-defined forms. In the primary form the symptoms presented were not associated with other abdominal lesions. The process was one of thrombosis or embolism due to remote causes, as from the heart valves. Its practical interest lay in the fact that the surgeon might operate for the relief of intestinal obstruction, and at operation would think that he had been dealing with a self reduced volvulus. If, on the other hand, a frank gangrene was found—a rare finding in early cases—he might resect the intestine without suspecting the cause of the condition. The second form occurred as a complication of various septic conditions, and it might be associated with the common forms of intestinal obstruction. As a complication of clean or aseptic surgery it was responsible for many deaths that were attributed to postoperative ileus. The symptomatology of these cases was susceptible of another classification into fulminating and phlegmatic, both of which might be either primary or secondary. There might be found considerable free fluid in the abdominal cavity ranging in color from a light yellowish to a dark brown. The blood vessels were cyanosed and dark. Gangrene might be present or there might be mottled segments of intestine alternating with dark red ones. At times there might be a small oval area of necrosis. The peritoneum, except in areas where there might be local death, had not lost its glistening appearance. The involved coils were not distinct and lay inert and half filled with liquid, looking very much like a rubber glove with a little water in it. If handled the coils gave a peculiar sensation of weight and thickness. The mesentery was heavy and soggy, and thrombosed vessels might be seen if not obscured by tumefaction. One or two folds of the mesentery might hang down over the sacral promontory, and give the impression of being adherent, but this was produced by the weight of the liquid contents. In all of his cases the middle one-third of the small intestine was involved and the mesentery appeared to have a low attachment; whether this had anything to do with the production of the condition he was unable to say. The fulminating cases presented a symptom complex which constituted a disease entity. The phlegmatic types were less easily recognized, and especially if they were associated with preexisting trouble. The fulminating type was characterized by pain, sudden and violent, if primary, or if secondary by the same kind of pain in connection with the preexisting symptoms. The pain was worse on the left side. In the phlegmatic type the pain was not sudden or severe, but varied from a vague unrest to a severe cramp, and when this form was superimposed on another lesion it was very insidious. Vomiting occurred in all the forms, was coincident with the pain, sometimes became stertorous, and tended to cease spontaneously in a few hours, when the pressure above the lesion had been relieved. Bleeding was said to be characteristic but was found in only two cases in this series. The muscle rigidity was not to be compared with that found in other equally severe conditions. The abdomen was not distended as in peritonitis. The condition was afebril, and the pulse soft and irregular. In the fulminating cases the patient was more or less in shock. Mesenteric vascular occlusion was a disease of adult life, more than 70 per cent. of the cases being in individuals over 45 years of age. The condition might be mistaken for pancreatitis or rupture of a viscus. Moynihan stated that in this condition no surgeon could show a mortality of less than 50 per cent. The treatment was purely surgical, consisting of wide excision of the involved coils of intestine and anastomosis.

Dr. JOHNSTON said that where gangrene had not developed one always found a mottling of the mesentery due to ecchymotic spots, and on that the diagnosis could be made.

Some Special Points in the Surgery of the Gallbladder.—Dr. GEORGE W. CRILE of Cleveland, Ohio, made this presentation which was illustrated with lantern slides. He described the experience of his associate and himself in 1,325 operations on the gallbladder and ducts from the standpoint of the difficulties and failures that they had met with. Among the questions considered were: How they might increase the certainty of relief? How they might decrease the risk from hemorrhage? What was the incision of choice? When should the common duct be drained? Hemorrhage might be met by transfusion. The best incision in operating on the common duct was parallel to the costal border; this did not divide many nerve fibres and secured against post-operative hernia. The incision should be long enough to insure adequate exposure. In cholecystotomy the best drainage was from the dependent point, and frequently this was obtained by a counter incision at the bottom of Morrison's pouch. In fulminating acute cases the only immediate procedure was to establish gallbladder drainage. It was very desirable to carry the acute gallbladder to the subacute stage before final operation. When this acute condition subsided and the patient's condition was stabilized cholecystectomy was the procedure of choice in those cases giving a history of recurrent attacks of cholecystitis. In severe cases of acute cholecystitis he used a short incision, a round tube, plenty of gauze about the opening and no stitches. The general principle of adequate exposure held for operations on the common duct as for those on the abdomen. In discussing cholecystectomy versus cholecystotomy, Dr. Crile said that in the absence of the gallbladder the common duct compensated by storing bile and that predisposed to the formation of stone and a recurrence of symptoms, so that the removal of the gallbladder was not without some unfavorable consequences. If the mucous membrane of the gallbladder was gangrenous, if the wall was thickened, or if stones were imbedded, and after drainage there had been a recurrence of periodical attacks of cholecystitis with obstruction and infection, then cholecystectomy was indicated. If the gallbladder and cystic duct were normal, no matter what the size of the stone there would rarely be a cycle of recurrent attacks and cholecystotomy would fulfill the requirements. In removing the gallbladder there should be a free exposure through an ample incision so as to give free access to its base. The gallbladder should be dissected free by sharp dissection without injury to the liver. The entire gallbladder should be freed from its attachments so that ample opportunity might be given for determining where the gallbladder ended. The cystic duct should likewise be dissected free so that the exact point where division should be made between the gallbladder and the cystic could be determined. The cystic duct should be taken off near the common duct. The clinical results following cholecystectomy were as much better than those following cholecystotomy as were those of nephrectomy better thon those of nephrotomy. They were now doing about sixty cholecystectomies to forty cholecystotomies. In doing a cholecystectomy a careful dissection should be done so that the surgeon would not be at a disadvantage later if he were called upon to operate upon the common duct. In stricture of the common duct an anastomosis might be made between the gallbladder and duodenum at a point of selection. Liver shock was a common cause of death after gallbladder operations and was due to failure of the liver cells to perform their function. Its prevention was secured by the avoidance of liver cell depression. The depression of the liver cells was increased by trauma and by low blood pressure, and that meant suboxidation. To prevent this light gas anesthesia should be employed, the operation should be as brief as was compatible with good surgery, blood transfusion should be given early, and heat should be applied over the whole abdomen. The finger should be used as a probe in the common duct. He also objects to the use of a tube in the common duct.

Dr. CLARENCE MCWILLIAMS of New York suggested the intravenous infusion of calcium lactate. One could estimate the coagulation time of the blood and then give 15 grains of calcium lactate, and again test the coagulation time of the blood. On the following morning a second infusion of 15 grains of calcium lactate could be given, and the coagulation time again tested. He cited a case coming under his observation recently in which two infusions of calcium lactate and two blood transfusions were given without any effect, and the patient died.

Dr. PARKER SYMS of New York said he was glad

to hear Dr. Crile take the stand that he did in reference to the selection of cases suitable for cholecystectomy. He was one of those who believed the gallbladder served some important function. Personally he thought cholecystectomy should only be performed for good reasons, as when there was actual pathology of the gallbladder or danger of permanent obstruction of the cystic or common ducts. He had found the maximum amount of bile drained to be about 39 ounces in twenty-four hours. Dr. Syms cited one case in which a gallon of fluid was drained in each of two successive days and the woman at the same time had a watery diarrhea. The report from the laboratory came back stating that the fluid showed a trace of bile.

Dr. J. TINKLER of Buffalo said that as to the question of the drainage of the common duct he was inclined to favor draining it and was also in favor of draining through Morrison's pouch.

Dr. JOHNSON said he would like to hear something about the beginnings of gallbladder disease. He thought the early toxic vomiting of pregnancy was one of the starting points of biliary disease. According to Dr. Mayo 90 per cent. of the cases began in pregnancy.

Dr. CRILE said he felt as one of the speakers had said that we did not know just what to do in these cases. He believed that gallbladder disease was often the result of other processes. Pregnancy made a great demand on liver function. Where there was excessive nausea and vomiting they had been trying the plan of introducing nourishment through the duodenal tube and in that way the patient retained the nourishment. He could not say as yet how valuable this procedure would prove to be.

Application of the Methods Developed During the War to the Fractures of Civil Life.—Dr. JOSEPH A. BLAKE made this presentation which consisted of a lantern slide demonstration of the overhead suspension and traction treatment of fractures which was developed during the war and which was now being used in the treatment of fractures at Bellevue Hospital. He begged pardon for bringing up anything connected with the war, but said they had learned some things worth repeating. At the beginning of the war they had treated fractures by the application of plaster of paris, but they soon found that they would have to develop some method that would permit of better access to the wounds and more susceptible of variation so they came to use wire splints, and in 1917 and 1918 these were well established in the French and English armies. They were at first much hampered by the old opinions as to the treatment of fractures, namely, that they should be fixed as much as possible. However, they found that the further they got away from the old idea of fixation the better were the results obtained. In fractures of the long bones it was perfectly easy to fix the distal fragment, but the difficulty came in fixing the upper or proximal fragment to the lower fragment. The principle upon which the newer methods of treatment were based was that when the proximal fragment was at physiological rest, that was in the position in which antagonistic muscles had brought it, it would not have much tendency to move in either direction, and if the upper fragment was in that position, the other fragment could be readily moved. Having placed the upper fragment in the position of physiological rest the distal fragment was brought into line with it, and then the whole extremity could be moved without moving the fracture. Dr. Blake then demonstrated the use of the overhead suspension frame in high fractures of the humerus. He said it gave uniformly good results, the only objection to it being that the patient had to remain in bed, and that was not an objection considering the rapidity with which repair took place, and the fact that function was absolutely maintained. After a time he left the arm free during the day and put it back in the suspension apparatus at night, and in this way union was often obtained in eighteen or twenty days. In fractures of the forearm the fragments were not suspended in the same plane, one being suspended mesial to the other. In the application of traction they made use of the glued cotton glove with curtain rings sewed to each finger tip. This permitted of even traction, or traction might be applied to individual fingers. The Blake-Keller half ring thigh and leg splint was shown. This splint had proven of great value in the transportation of men with fractured femur. This splint and the Thomas arm splints should form a part of the equipment of every ambulance. The old idea of fixation by plaster and other splints had been exploded, having been found to be not only to be unnecessary but pernicious. He hoped that they would be able to extend some of these methods which had been so valuable in the treatment of fractures during the war to the treatment of industrial injuries. They shortened the period of convalescence and they did away with at least 50 per cent. of the incapacity resulting from other methods. There were at least three-quarters of a million industrial injuries in this country every year and these patients should have the benefit of these newer methods.

The Abduction Treatment of Fractures of the Neck of the Femur.—Dr. ROYAL WHITMAN made this presentation, which was illustrated by lantern slides. He stated that he had presented the method before but that the results obtained by it had been so highly satisfactory that there was no reason for abandoning it. It was essential for the restoration of function that deformity be reduced and for union that the fractured surfaces be fixed in contact. Contact could be assured only by adapting the outward fracture to the inward. To accomplish this the patient must be anesthetized. The shortening was then reduced by direct traction. The thigh having been lifted to the proper plane, was then abducted to the normal limit. Abduction was effected with the perineum against a perineal support. Abduction turned the fractured surface down to meet that head of the femur; it made the capsule tense and aligned fragments; it relaxed muscles whose contraction tended to displace fragments; it apposed the trochanter to the side of the pelvis, or if the fracture was near the head engaged the neck beneath the rim of the acetabulum and provided a mechanical check to displacement. What was classed as impacted fracture was usually a complete fracture. After reduction the body and limb were covered with sheet wadding and cotton flannel bandages, all bony points being carefully protected, and a long plaster spica support was applied. With the fracture thus dressed the patient could be turned completely over on the abdomen so that bed sores could be avoided and also the danger from hypostatic pneumonia. The head of the bed was elevated at an angle of 25°, providing a semi-reclining position which favored the nutrition of the injured parts. The neck of the femur in young, vigorous persons might be broken by but slight violence and the fracture might not cause complete disability. The bad prognosis usually given for fractures of the femur was not warranted, but was largely due to incorrect technique. He had treated many elderly persons by the abduction method with gratifying results. His oldest patient was a woman 89 years of age who lived to be 93. Dr. Whitman said he preferred to treat fractures of the femur rather than other types of fractures because his results were uniformly good and as good were unexpected he received great credit. The traditional teaching that the prognosis of fractures of the neck of the femur was bad was incorrect, since with proper technique one could secure a high percentage of successes.

Dr. JOHN F. CONNERS of New York said that Dr. Blake had done great service in helping to develop these methods. He would like to know his views with reference to the use of the calipers in fractures of the femur. He thought Dr. Blake had sounded the death knell in the treatment of fractures by plaster of paris.

Dr. EDWIN BEER of New York said he had not heard Dr. Whitman give his percentage of successes in the treatment of fractures of the neck of the femur.

Dr. BLAKE said the use of the calipers was extremely important in the treatment of high fractures of the femur. In fractures of the femur there was a tendency for the fragments to be forced outward and consolidation was extremely slow, so these patients should not be allowed to walk until cancellous bone was established. He had been impressed by Dr. Whitman's demonstration and believed that plaster of paris had its place, but he had wished to emphasize that there

were other methods of treatment and that we had gone too far in the use of plaster of paris. There was no question but that Dr. Whitman's abduction treatment of fractures of the neck of the femur was excellent.

Dr. WHITMAN said he could not agree that the death knell of plaster of paris had been sounded. He thought it was going to become very popular. It required skill in application and one had to be sure that the fragments were in apposition. Then, again, one had to use the materials available. As to his results he had refrained from quoting them because he feared he would be accused of exaggeration. The point he wished to emphasize particularly was that fractures of the femur could be treated with the same expectation of good results as other fractures. After fractures of the neck of the femur patients were not allowed to bear weight under six months.

Third Day—Thursday March 25.

A Type of Cystic Kidney Amenable to Surgical Treatment.—Dr. FREDERICK J. PARMENTER of Buffalo presented this paper, which he illustrated by means of lantern slides. He said there were two theories to account for cystic kidney: (1) The theory of congenital maldevelopment which assumed that the secreting and collecting tubules failed to connect so that there was no outlet for the secretion; (2) that epithelial proliferation took place which might go on to true tumor formation. A third theory held that there might be a combination of these two conditions with a predominance of the one or the other. These cystic conditions might increase to such an extent that the entire abdomen would be occupied by the diseased kidney. Cystic disease of the liver was associated with cystic kidney in 28 per cent. of the cases. Polycystic disease of the kidney was always bilateral, and the practical point here was that one should never perform a nephrectomy for polycystic kidney. The condition might occur in infancy or after 40 years of age. Heredity seemed to play a striking rôle. When the condition occurred in infancy it was usually associated with other congenital defects. The symptoms might be associated with renal compensation or renal decompensation. The disease might progress to the stage of renal decompensation without the patient being aware of its presence. There might be dull, aching pain, which might be diagnosed as due to calculus of the ureter or ptosis of the kidney. Hematuria might occur independently of pain. In some of these kidneys the parenchyma might appear to be almost entirely destroyed and yet kidney function might be good. Hydro- or pyo-nephritis might be coexistent due to kinking of the ureter caused by the heavy ptosed kidney. The symptoms during the period of decompensation resembled those of chronic interstitial nephritis. The right kidney was often less extensively involved than the left. The treatment was to relieve pain and suffering, to save the parenchyma, and to prevent further atrophy. Operation was therefore indicated and consisted in puncturing as many of the cysts as possible, and if a ureter was found kinked it was straightened, or if a kidney was ptosed it was sutured in place. The second group of cystic kidneys was rare. This type of kidney did not kill the patient, and here excision of the cyst was indicated and not nephrectomy. Colheim attributed this form of cystic kidney to cell rests which became stimulated and began to secrete with the result that a true retention cyst was formed. The condition was unilateral. The picture presented, however, was similar to that of the polycystic kidney. The disease was slightly more frequent in women, and adults were mostly affected, it being rare to find a case under twenty years of age. Pain and swelling were usually present, and the kidney function was normal. The patients usually appeared in good health. Malignancy could be ruled out by the good general condition of the patient and the absence of metastases. In this form of cystic kidney the prognosis was excellent if the kidney was exposed and the cyst excised.

Urological Diagnosis in the Practice of the General Surgeon.—Dr. LEO BUERGER presented this paper, which was read by Dr. Leo Edelman, who stated that the object of the paper was to show the great amount of light which the general surgeon might obtain by making use of the specialist's knowledge. In no field was this truer than in that of urology. Modern urological investigation with highly developed urological instruments and practice in their use made available to the urologist many special procedures which were not ordinarily employed by the general surgeon. The general surgeon could cooperate with the urologist to his own advantage and to that of his patient. There was great need for educating young men in the field of urological diagnosis, for here many mistakes were made. To mention a few of these, calculus of the ureter might give symptoms simulating intestinal obstruction and even peritonitis, and operation might be performed when it would have been possible to remove the calculus through the urinary tract. Urinary calculus in the lumbar region might be taken for retrocecal appendicitis. When there were signs of urinary retention, with or without a scratch on the wax-tipped catheter, calculus should be suspected. In some cases of supposed subacute or chronic appendicitis a vaginal examination revealed the presence of ureteral calculus low down. Tuberculous nodules in the ureter might be mistaken for calculi. Ovarian trouble had been diagnosed in cases in which a cystoscopic examination would have revealed intraureteral débris. The indications and methods of employing the retention catheter were discussed. A lantern slide demonstration showed what the urologist could discover by means of the shadow-graph catheter; the pyelograph, which though its use was restricted was important in certain cases; the baby cystoscope, which had enabled them to make great advances in the diagnosis and treatment of pyelitis in children; the Buerger operating cystoscope which carried a scissors-like instrument which made possible certain operative procedures on the bladder, and the direct, indirect, and retrograde cystoscope.

Dr. A. W. BRASH of North Germantown said he thought Dr. Buerger should be thanked for his thorough exposition of the subject of urology. The paper might have been entitled the differential diagnosis of acute abdominal conditions. It was quite true that stones in the ureter would give the symptoms of intestinal obstruction. Dr. Buerger had also shown what could be done in the field of pyelography. He had demonstrated that many conditions could be discovered only by means of explorations such as he had described.

The Rôle of the Colon Bacillus in Infections of the Kidney.—Dr. HUGH CABOT of Ann Arbor, Mich., presented this paper by invitation. He said that, having excluded tuberculosis, the colon bacillus was found to be the infecting organism in a large percentage of infections of the kidney. The number of cases of these infections did not seem to be decreasing, so that they could not view their progress in this direction with complacency. The most common and perhaps the most important kidney lesion was pyelitis. Of this condition there were two groups of cases. In the first there was no demonstrable reason for the infection in the urinary tract. He discussed the second class first because he said they presented the least difficulty. They were the cases dependent upon stricture, stone in the bladder, or other obstruction to the urinary outflow in the urinary tract itself. Such obstruction, however, was not only the only factor, but was merely instrumental in preparing the soil for infection. He did not believe instrumentation of the urinary tract was frequently the cause of infection. Where there was residual urine associated with lowered resistance the soil was prepared for infection. The so-called catheter system following operation was open to criticism. It was too much the custom to delay catheterization and trust that retention would not occur, and it was too frequently assumed that catheterization was responsible for infection. So long as patients were catheterized by the clock just so long would infections continue to be a reproach to the physician. All these patients should be regarded as likely to have retention. The bladder should never be allowed to became distended above twelve ounces. If early catheterization were carried out postoperative cystitis would become a rarity. The first group of cases was that in which kidney function might be below normal and the cause lay outside the urinary tract. In this group pressure from the outside produced interference with the urinary outflow, leading to congestion which prepared the soil for the infecting organism. In this group the pyelitis of pregnancy was discussed as

well as the so-called spontaneous cases associated with disease of the large intestine, such as mucus colitis and ulcerative colitis. There were also a group of cases occurring in adult life, particularly in women suffering from constipation and visceroptosis, and another group of female children in which we have been accustomed to blame the condition on the anatomical conformation. If these infections in female children were due to the introduction of the colon bacillus by way of the urethra it was strange that they were not more common. Experiment had shown that introduction of the colon bacillus into the bladder did not produce pyelitis and clinical experience was against this view. It might well be that the colon bacilli affected the kidneys of those who had little resistance. The use of formaldehyde and local irrigation of the kidneys had been much in vogue, but it had failed to live up to its temporary reputation. It was quite strange that patients with a stormy onset and severe symptoms were most likely to go on to complete recovery, while chronic cases were likely to resist treatment. It appeared to follow that the severe cases recovered because an immunity was produced. Attempts with autogenous vaccines might at times relieve the symptoms, but failed to remove the infection. He was not sure they had pushed the use of autogenous vaccines to their logical conclusion. Might it not be better to use them during the acute rather than in the chronic stage? Or might it not be better to push the vaccines until they produced symptoms and sensitization? There was need of further study of bacilluria and perhaps conditions in the large intestine might give a clue to the treatment of pyelitis.

Dr. Edward L. Keyes, Jr., of New York asked Dr. Cabot to say a word as to the influence of the passage of instruments in the ureter in relation to its influence on pyelitis. Attempts to wash out the pelvis of the kidney had not proved satisfactory in his hands. It was possible that a certain amount of benefit might be due to the straightening out of the ureter by the passage of the instrument employed in giving the irrigation.

Dr. A. W. Brash of North Germantown questioned whether the large intestine was the etiological factor in pyelitis. It was his impression that the connection between the colon and the kidney was very limited. In treating pyelitis they removed the foci of infection in the teeth or tonsils if such was present and then employed lavage of the kidney pelvis with silver nitrate, placing the patient in the Trendelenburg position. They passed good sized bulbs that straightened out any stricture that was present, and they believed they cured pyelitis in a large percentage of cases.

Dr. Edwin Beer of New York asked Dr. Cabot to say whether he was of the opinion that preliminary vaccination prevented complications with the colon bacillus following prostatectomy. He would like to hear Dr. Cabot discuss the question of ureteral catheter lavage of the pelvis of the kidney. Personally he had seen absolutely no results from this procedure. In cases of acute pyelitis naturally one did not care to irrigate the pelvis of the kidney, but there might be some benefit from washing out the ureter which might wash out mucus plugs that were causing some interference with the outflow of urine. The reason they did not get results by this procedure was that they did not know what they were treating. The only diagnosis they made was made late when pus made its appearance. The diagnosis of kidney involvement was not made until after the fifth day. He did not believe lavage was effective. With the patient in the Trendelenburg position the silver nitrate might go to the pelvis of the kidney, but he doubted if it reached foci of infection in the parenchyma.

Dr. Cabot said the question he had wanted to hear discussed was the possibility of the sensitization of the kidney with foreign protein. Dr. Keyes had asked a question which he could not answer. It was, however, beyond doubt that occasionally there was a case in one's experience in which the use of the ureteral catheter with or without lavage of the kidney had produced very spectacular results. He could not subscribe to the Huenner doctrine of stricture of the ureter. It did not seem that these cases occurred in his experience. He had been asked whether he had retreated from his position in regard to certain anatomical relations which might account for the frequency of pyelitis in little girls. The difficulty here was that there had not been produced a sufficient amount of good work to settle that question one way or the other. Dr. Grimes and himself had done some work in studying the length and position of the large intestine in females as compared with males; it was possible that it might be shown that there was a definite anatomical difference, but this had not been shown thus far. As to the relation of the intestines to the kidney he did not agree with Dr. Brash. The relation between the intestine and the kidney was very clear. He had a series of twenty-five men between the ages of 25 and 35 years whose urinary tract was sound, men in good circumstances and living out of town, who had had acute illness characterized by fever, diarrhea and evidence of acute colitis, and it was observed that in a few days the colon bacilli were passed in the urine. In many after a time the colon bacilli disappeared from the urine, but later they would again have an acute attack, with symptoms of kidney infection, fever, and bacilluria. The relation between pyelitis and ulcerative colitis was often very striking. Dr. Brash had laid a good deal of stress on the importance of the removal of focal infections elsewhere in the body. Such infections were occasionally due to the colon bacilli, but they were oftener due to the streptococcus group and the condition he was talking about had nothing to do with that, for he did not believe that the streptococcus produced pyelitis. He did believe, however, that focal infection had a part in keeping these people under water, and he believed in a search for focal infection, but he doubted that there was a connection between colon bacillus infection of the kidney and infection of the mouth and teeth. As to the effect of silver nitrate, it might affect the organisms in the superficial epithelium and it might release organisms deeper down, but he doubted if silver nitrate did more than ameliorate symptoms. Unless the colon bacilli were permanently eliminated the case did not stay cured. In the group of little girls he should hesitate to use the cystoscope or to catheterize the kidney; in fact, he did not believe local treatment would be of much help in this group. He seemed inclined to believe hope lay in vaccines, but here the difficulty was that we had no measure of immunity and we did not know whether immunity was produced by the vaccines they were using. There were many strains of colon bacilli and if we were not vaccinating against the strains that were producing the pyelitis, we could not produce an immunity against those organisms.

Surgical and Non-Surgical Treatment of the Prostate and Seminal Vesicles in Arthritis.—Dr. Oswald S. Lowsley of New York presented this paper, which he illustrated with lantern slides. He stated that his communication was intended to encourage men in general surgery and medicine to consider the urinary tract in search for the cause of arthritis. The teeth, the tonsils, the sinuses, and various other focal infections had received the attention in respect to their relation to arthritis and he wished to call attention to the part played by the prostate gland and the seminal vesicles in the production of arthritis. His observations were based on the study of 100 cases of arthritis in the urological department of Bellevue Hospital. The ages of these patients ranged from 17 to 51 years, the average age being 29 1/3 years. The season of the year did not seem to make any difference except that there were not quite so many cases during the summer months. The joints affected in the order of frequency were the knee in 53, the ankle in 44, the wrist in 30, and the foot in 26. The infection was traced to the teeth in 31 cases, to the tonsils in 10. Twenty-three per cent. of the series denied having had gonorrhea. The impression that infection arising from the prostate and seminal vesicles was usually gonorrheal was incorrect. An analysis of these cases showed other organisms predominating in this locality, such as the *Staphylococcus aureus*, *Streptococcus viridans*, and other form of streptococci. In three of the cases brilliant results were obtained with vaccines. A number of cases were successfully treated by the heavy cast and steaming. Ten cases were treated surgically with good result. Where there was chronic seminal vesiculitis seminal vesiculectomy was preferable

to vesiculotomy. Of 50 cases of polyarthritis in which infection from other sources was eliminated, examination of the prostate and seminal vesicles showed these to be the source of the infection. In searching for the source of infection in any case of arthritis the prostate and seminal vesicles should not be overlooked. Autogenous vaccines were extremely valuable in some cases used in conjunction with other methods of treatment.

Dr. Frederick W. Parmenter of Buffalo called attention to the fact that the anterior urethra during an acute attack of gonorrhea might be the source of arthritis. In the treatment of acute gonorrheal infection it was often surprising to see a rapid improvement in the condition of the prostate and seminal vesicles, while the general condition did not improve. A study of some of these cases showed that they had bad teeth and after their teeth were taken care of the gonorrheal arthritis cleared up. It would seem that in such cases the focal infection had replaced the gonorrheal infection.

Dr. Lowsley said he was glad that Dr. Parmenter had called attention to the possibility of arthritis being caused by the acute infection; that was borne out by his experience and he had even seen death from gonorrheal septicemia.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

California State Board of Examiners.

October, 1919.

ANATOMY AND HISTOLOGY.

1. Describe the lacrymal apparatus.
2. Discuss the histology of the cornea.
3. Locate and give the relation of the prostate gland.
4. Give the histology of the prostate gland.
5. Locate and give relations of the parotid gland.
6. Give histology of the parotid gland.
7. If the radial (musculospiral) nerve be severed, what structure distal to the cut will be affected?
8. Indicate by diagram the important tracts, and the distribution of nerve tissue, in a cross section of the spinal cord in the mid-dorsal region.
9. Describe fully the sacroiliac articulation.
10. Give origin, insertion and nerve supply of the sterno-mastoid muscle; action when acting singly and together.
11. Locate and give relations of thyroid gland.
12. Give histology of the thyroid gland.

PHYSIOLOGY.

1. How is body heat maintained? What are the physiological aspects of fever?
2. Discuss briefly (*a*) phagocytosis, (*b*) diapedesis.
3. What is the composition and the action of bile?
4. Classify and give function of white blood corpuscles.
5. Give the physiological action of the pneumogastric nerve.
6. Describe the heart sounds; what causes them?
7. Describe the process and stimulation of respiration.
8. Name the enzymes and describe their function.
9. Discuss the factors which maintain blood pressure.
10. Discuss cerebrospinal fluid.
11. Describe lymph, its function, its circulation.
12. What is the effect of complete paralysis of the (*a*) third cranial nerve, (*b*) trigeminus.

CHEMISTRY AND TOXICOLOGY.

(Answer ten questions only.)

1. What are the metals of the arsenic group?
2. What two solutions of arsenic are official?
3. Silver nitrate. Give its appearance; how prepared; symbol; synonyms. What percent may be used in the eye and in the throat.
4. What do you understand by the term colloidal chemistry?
5. What is a calorie? Explain the calorie method of feeding.
6. Classify foods. Discuss one class.
7. What are enzymes? Discuss their characteristics.
8. (*a*) What constitutes metabolism? (*b*) What is a nitrogenous equilibrium?
9. What is a lethal dose of: Tincture of aconite, tincture of belladonna, tincture of gelsemium?
10. What is the result of a tablespoonful of camphorated oil, if swallowed by a one-year-old child?
11. Give symptoms and treatment of poisoning by wood alcohol.
12. What is the chemical cause of death in inhaling illuminating gas? Give treatment.

ANSWERS.

ANATOMY AND HISTOLOGY.

1. The *lacrymal apparatus* consists of the lacrymal gland and its secretory ducts; the lacrymal canals, which carry the tears to the lacrymal sac, and the nasal duct, which carries them from the sac to the nose.

The *lacrymal gland* occupies a depression in the supero-external angle of the orbit; the anterior margin is connected to the back part of the upper eyelid. The ducts (twelve or fourteen) open by apertures, placed in a row, at the inner surface of the upper lid.

The *lacrymal canals* commence at the *puncta lacrymalia*, which are the openings of the canaliculi, and, arching in the free edge of the lid, pass inward to open into the *lacrymal sac*.

The *lacrymal sac* is placed in a groove formed by the lacrymal bone and the nasal process of the superior maxilla, being behind the tendo oculi and in front of the tensor tarsi; it is the dilated upper end of the nasal duct.

The *nasal duct*, formed by the lacrymal, superior maxilla, and inferior turbinal bones, leads from the lacrymal sac to the inferior meatus of the nose, where it opens, the aperture being partly guarded by a valve formed of the mucous membrane. It is about one-half inch long, and is directed downward and slightly outward and backward.—(*Aids to Anatomy.*)

2. The *cornea* consists of five layers: (1) An anterior layer of stratified squamous epithelium; (2) an anterior elastic membrane, also known as Bowman's membrane; (3) the substantia propria, consisting of connective tissue fibrils which are cemented together to form bundles and lamellæ; (4) the posterior elastic membrane of Descemet, similar to the anterior elastic membrane, but thinner; (5) the posterior endothelium of Descemet, consisting of one layer of flat hexagonal cells.

3. The prostate gland is about the size and shape of a horse-chestnut, and surrounds the neck of the bladder and first part of the urethra in the male. It is surrounded by a dense capsule, and consists of three lobes (two lateral and one middle); it is pierced by the ejaculatory ducts and by the urethra. Its base is attached to the base of the bladder, and its apex is in relation with the posterior layer of the triangular ligament and the compressor urethræ muscle. The posterior surface is in relation with the rectum and is about an inch and a half from the anus.

Relations of Prostate. *Anteriorly:* Symphysis pubis, anterior ligaments of bladder, branches of dorsal vein of penis. *Posteriorly:* Rectum. *Laterally:* Levator ani. *Base:* Surrounds neck of bladder, seminal vesicles, and vasa deferentia. The *apex* rests on triangular ligament.

4. *Structure of prostate.* "The prostate is a compound tubulo-alveolar gland whose ducts open into the prostate portion of the urethra. Smooth muscle fibers not only surround the organ, but interlace radially toward its center, forming a network in whose meshes the glandular parts are located. Areolar tissue and blood-vessels accompany the muscle tissue. The alveoli of the glands are lined by simple columnar epithelium, which sometimes show two rows of nuclei. These alveoli contain a serous acid coagulum and usually oval laminated concretions called *prostatic bodies*. The latter are more numerous in old men. The numerous excretory ducts unite to form twelve to fifteen collecting tubes which open into the urethra, most of them into the *prostatic sinus*. These ducts are lined by simple columnar epithelium, except near their termina-

tions, where it is transitional. The organ dorsal or in front of the urethra is mostly smooth muscle tissue."—(Hill's *Histology.*)

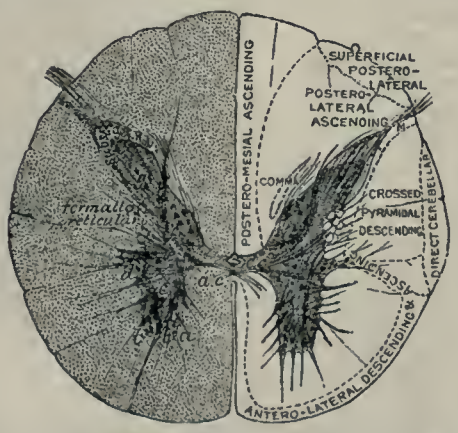
5. The *parotid gland* occupies the space in front of the ear, bounded below by the angle of the jaw, and a line extended from it to the mastoid process, above by the zygoma, in front by the masseter muscle, and behind by the mastoid process, the external meatus, and the digastric muscle. The external carotid artery and branches, the internal maxillary, temporal and temporo-maxillary veins, the facial nerve, and the great auricular nerve pass through it.

RELATIONS: *Externally,* it is covered by the skin, platysma myoides, and parotid fascia; *internally,* it is in relation with the styloid process and its muscles, internal carotid artery and internal jugular vein.

6. *Histology of the parotid gland.* "The parotid gland is a compound alveolar gland and consists of small, serous acini, lined by cells adapted to fit these alveoli. The actively secreting cell has a very granular protoplasm, but that of the resting cell contains but few granules. As the granules increase, the protoplasm decreases, until expulsion of the secretion, and then the protoplasm again increases. Secretory capillaries exist between the cells."—(Radasch's *Histology.*)

7. *Total division of the musculospiral nerve* causes the following symptoms: A. Anesthesia. If the nerve is divided in the upper third of the arm—*i.e.* above the origin of its external cutaneous branch—there is loss of both epicritic and protopathic sensation over the radial half of the dorsum of the hand. Section of the radial nerve in the upper third of the forearm causes no loss of sensation, which is supplied to the back of the hand by the external cutaneous of the brachial plexus; but section in the lower third causes a limited loss of epicritic sense over the back of the thumb. B. Paralysis of the following groups of muscles: (1) Of the extensor of the forearm (triceps); hence the forearm can only be extended by its own weight. (2) Of the long and short supinators; hence the hand is pronated, the only supinator remaining being the biceps. (3) Of the radial and ulnar extensors of the wrist; hence wrist drop. (4) Of the extensors of the fingers and thumb, which either hang limp and motionless, or may be bent up into the palm from the unopposed action of the flexor muscles. If, however, the wrist and proximal phalanges are supported and extended, the terminal phalanges can be straightened by the action of the interossei and lumbricales.—(From Rose and Carless' *Surgery.*)

8.



Section of human spinal cord from the mid-dorsal region, showing the principal groups of nerve-cells, and on the right side of the section the conducting tracts; *a, b, c,* groups of cells of the anterior horn; *d,* cells of the lateral horn; *e,* middle group of cells; *f,* cells of Clarke's column; *g,* cells of the posterior horn; *c.c,* central canal; *a.c,* anterior commissure. (From Schäfer's *Histology.*)

9. The *sacroiliac articulation* is an amphiarthroidal joint existing between the articular surfaces of the ilium and the sacrum. It is connected by three ligaments, the anterior sacroiliac, the posterior sacroiliac, and the interosseous ligaments. The anterior ligament connects the anterior surfaces of the two bones. The posterior ligament is the stronger and consists of the short and long sacroiliac ligaments. The interosseous ligament is completely covered by the posterior ligament. The arteries are derived from the gluteal, sacral, spinal, and ilio-lumbar; the nerves from the lumbo-sacral and posterior sacral cords.

10. STERNOMASTOID. *Origin:* Upper and outer part of the anterior surface of the manubrium sterni, and upper surface of the clavicle at its sternal end. *Insertion:* Outer surface of mastoid process of the temporal bone, and outer part of the superior curved line of the occipital bone. *Action:* To flex the head to the same side as the muscle; the two acting together flex the head on the thorax and also raise the upper thoracic wall in forced inspiration. *Nerve supply:* The spinal accessory nerve and a branch from the cervical plexus.

11. The *thyroid gland* is situated on the sides and in front of the upper part of the trachea, and extends upward on each side of the larynx. The lobes extend from about the middle of the thyroid cartilage to the fifth or sixth tracheal ring; the isthmus generally covers the second and third tracheal rings.

RELATIONS. *Antero-external:* Deep cervical fascia, sternomastoid, sternothyroid, and sternohyoid muscles. *Postero-internal:* Trachea, cricoid, and thyroid cartilages, inferior constrictor muscle, inferior thyroid artery, recurrent laryngeal nerve and esophagus (on left side). *Externally:* Sheath of carotid artery and internal jugular vein.

12. The thyroid gland "is surrounded by a capsule that sends in trabeculæ, which divide the gland into lobes and lobules. These divisions are irregular, and the lobules are composed of a number of short tubules, sometimes called follicles. Each tubule is lined by cuboidal epithelial cells that rest upon a basement membrane; outside of this is the intralobular, or intertubular, connective tissue that supports the blood-vessels. In the tubules is seen a peculiar, homogeneous substance, the colloid substance, that is supposedly the result of the activity of the cells. It has a yellowish color, and as blood cells are frequently seen in it, the color may be due to the hemoglobin from these."—(Radasch's *Compend of Histology.*)

PHYSIOLOGY.

1. The heat of the body is *maintained* by the thermotactic centers in the brain and cord keeping an equilibrium between the heat gained or produced in the body and the heat lost. *Heat is produced in the body* by: (1) Muscular action: (2) the action of the glands, chiefly of the liver; (3) the food and drink ingested; (4) the brain; (5) the heart; and (6) the thermogenetic centers in the brain, pons, medulla, and spinal cord. *Heat is given off from the body* by: (1) The skin, through evaporation, radiation and conduction; (2) the expired air; (3) the excretions—urine and feces.

Fever. "The rise of temperature in fever depends primarily upon an increase in the metabolic combustion. Oxygen is used in larger amount than is usual, while the combustion products, carbonic acid, and the nitrogenous substances, urea, uric acid, etc., are excreted in greater abundance. This increased combustion is usually associated with disturbances of digestion and assimilation of food, so that the abnormal heat production is effected largely at the expense of the body proteids and the various tissues and organs concerned in metabolism. But with the increased heat production there usually occur, in the earlier periods of fever, such disturbances in the vasomotor control of the cutaneous blood-vessels as lead to their contraction. Thus heat elimination is retarded. In later periods the vessels of the skin may dilate so that, in spite of its persistent dryness and lack of the cooling effect of sweat evaporation, there is an excessive loss of heat from this source. . . . In the great majority of cases fever is due to the presence in the body of deleterious substances, either introduced from without, or, more commonly produced within the body. These are most often formed in infections, and arise either from the growth in the tissues of pathogenic microorganisms or from the disintegration of their bodies; that is, they are toxins or endotoxins. But there is abundant evidence that fever is not infrequently due to perverted metabolism of the tissue cells, leading to the formation of toxic substances. Such self-engendered

substances are called autotoxins. The pyrexia of sunstroke is believed to be an example of this phase of autointoxication."—(Delafield and Prudden's *Pathology*).

2. *Phagocytosis.* The leucocytes (especially the polymorphonuclears) and certain other cells, notably endothelial cells, have the power of ingesting and removing, and in some cases of digesting, dead and inert matter or bacteria which may gain access to the tissues. This process is called phagocytosis.

Diapedesis is the term used by some writers to denote the wandering out of the red blood cells from the blood vessels during the early process of inflammation, that is, before inflammatory stasis occurs. Others use the term to denote the passage of the leucocytes through the vessel walls.

3. *Composition of bile:* Water and solids; the latter, about 15 per cent., consist of sodium taurocholate, sodium glycocholate, mucin, bile pigments (bilirubin and biliverdin), lecithin, cholesterin, neutral fats, and inorganic salts (NaCl, KCl and phosphates).

The *physiological action of the bile* is: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis; and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach, and thus inhibits peptic digestion; (7) it aids the pancreatic juice in digesting protein; (8) it has a very feeble antiseptic action.

4. *White blood corpuscles* are divided into (1) small mononuclear leucocytes, or lymphocytes; (2) large mononuclear, (3) transitional, (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. Their *functions* are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (4) they help to maintain the proper proteid content of the blood plasma.

5. *Physiological action of the pneumogastric nerve:* "Throughout its whole course the vagus contains both sensory and motor fibers. To summarize the many functions of this nerve . . . it may be said that it supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part, (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excitomotor* in coughing, vomiting, etc."—(Kirkes' *Physiology.*) It also supplies secretory nerves to the stomach.

6. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged, the second, or diastolic, sound is sharper and shorter. The sounds may be expressed by the syllables *lubb—dup.*

The first sound is heard best at the apex beat in the fifth left intercostal space; the second sound is heard best over the second right costal cartilage.

The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculo-ventricular valves; (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall.

The *second* sound is caused by the vibration due to the closure of the semilunar valves.

7. "Respiration is carried on under ordinary circumstances by the diaphragm and external intercostals enlarging the chest and sucking air into the lungs, followed almost immediately by the recoil of the elastic lungs and ribs forcing out the air so inspired. But when there is a more than ordinary venous condition of blood in the system greater efforts must be made to supply the lungs with oxygen, and muscles not ordinarily employed in the effort must be brought into play. The arms and scapulæ are fixed by seizing hold of some object, and by bringing into action the trapezius, levator anguli scapulæ, and rhomboidei, so as to make firm attachments for serratus magnus, pectorales and latissimus in their efforts to raise the ribs. Labored expiration in like manner brings extra muscles into play. In labored respiration the nostrils are expanded by the dilatores naris during inspiration, and resume their original size during expiration. The glottis is widely open during inspiration, while it is narrowed during expiration. These movements of the glottis occur during ordinary breathing, but are exaggerated during difficult breathing.

"Breathing is a reflex act, capable of being modified by the will. The nerve-center is situated in the medulla, the *afferent* nerves are the vagi; the *efferent* nerves are the phrenics, intercostals, etc. Respiration continues in the absence of consciousness and after the removal of the brain about the medulla; but destruction of a certain small portion of the medulla below the vasomotor center causes the movements at once to cease. This spot is called *nœud vital.* The center is influenced by impulses from without or within—a dash of cold water in the face, a cold bath, an emotion, venous blood in the pulmonary vessels, all call it into action. The center is probably automatic as well as reflex, section of the vagi, thereby interrupting the channel by which the afferent impulses reach it from the lungs, while interfering with the respiratory act does not stop its action. Automatic impulses descend from the center along the efferent nerves. Probably the venous blood circulating through the center itself supplies the stimulus."—(Ashby's *Physiology.*)

8. *Classification and function of enzymes.* Howell (*Physiology*) gives the following: 1. The protolytic or protein-splitting enzymes. Examples: pepsin of gastric juice, trypsin of pancreatic juice. They cause a hydrolytic cleavage of the protein molecule. 2. The amylolytic or starch-splitting enzymes. Examples: ptyalin or salivary diastase, amylase, or pancreatic diastase. Their action is closely similar to that of the classical enzyme of this group—diastase—found in germinating barley grains. They cause a hydrolytic cleavage of the starch molecule. 3. The lipolytic or fat-splitting enzymes. Example: the lipase found in the pancreatic secretion, in the liver, connective tissues, blood, etc. They cause a hydrolytic cleavage of the fat molecule. 4. The sugar-splitting enzymes. These again fall into two subgroups: (*a*) The inverting enzymes, which convert the double sugars or disaccharids into the monosaccharids. Examples: maltase, which splits maltose to dextrose; invertase, which splits cane-sugar to dextrose and levulose; and lactase, which splits milk-sugar (lactose) to dextrose and galactose. (*b*) The enzymes which split the monosaccharids. There is evidence of the presence in the tissues of an enzyme capable of splitting the sugar of the blood and tissues (dextrose) into lactic acid. 5. The coagulating enzymes, which convert soluble to insoluble proteins. Example: The coagulation of the casein of milk by rennin. 6. The oxidizing enzymes or oxidases. A group of enzymes which set up oxidation processes. 7. The deamidizing enzymes, such as adenase and guanase, which by hydrolytic cleavage split off an NH_2 group as ammonia.

9. *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the arterial walls, and the resistance of the capillaries. The normal arterial blood pressure varies; the systolic pressure being (in males) about 120 to 150 mm. of mercury, and the diastolic from about 90 to 120 mm. of mercury. In females, the pressure is from 10 to 15 mm. lower. Blood pressure is *maintained* by the contraction of the heart, the peripheral resistance, and the elasticity of the arterial walls.

Blood pressure is estimated by a sphygmomanometer.

Arterial pressure is produced and maintained by: The force and contraction of the left ventricle; the volume of blood pumped by the heart into the already full arteries; the action of the aortic semilunar valves in preventing regurgitation of the blood into the left ventricle when it goes into diastole: the elastic resiliency of the middle coats of the large arteries; the peripheral resistance exerted by the muscular wall of the arterioles, which are especially controlled by the

vasomotor nerves; the increased surface over which the blood flows through the capillaries; and the tension of the extravascular tissues. The *capillary pressure* depends upon the condition of the arterioles. If the arterioles to a part dilate, the capillary pressure rises; if they constrict the capillary pressure falls. If, however, the venous pressure is raised, the capillary pressure must consequently rise too. Gravity very materially influences the capillary pressure. The *venous pressure* is influenced by: The presence of valves, which prevent a backward flow; and respiratory movements.—(From Lyle's *Physiology.*)

10. "The *cerebrospinal fluid* is a clear, limpid, colorless fluid, with a specific gravity of 1006 and an alkaline reaction. In taste it is salty, resembling tears and sweat rather than lymph and blood. It varies in amount from 100 to 130 c.c., while the pressure under which it flows fluctuates between 40 and 150 mm. Its main constituents are water and sodium chloride. In addition it contains glucose, albumin, carbonates, phosphates, urea, about 55 per cent. of CO_2, traces of globulin the only protein material present, and a few cells. These cells are mononuclear, lymphocytic, and endothelial; in health their number varies from 2 to 10 per cubic centimeter. The cerebrospinal fluid is neither a mere exudate nor a true secretion. It is derived from the plasma of the blood by dialysis. Its main source is the epithelial cells lining the choroid plexus of the ventricles; additional sources are probably the perivascular system of the nervous tissues and possibly also the arachnoid villi. It has a definite circulation of its own, passing from the choroid plexus into the lateral ventricles, and from them, by way of the foramen of Monro, to the mid-ventricular system. It then escapes by way of the foramina of Magendie and Luschka, into the subarachnoid space. In the subarachnoid space it bathes both brain and cord, flowing from there by way of the arachnoid villi, the dural sinuses, the veins, and possibly the lymphatics into the circulation. The secretion is active and continuous, so that when withdrawn it promptly reforms, passing with each systole of the heart from the cranium to the spinal canal. It renews itself six or seven times in twenty-four hours and consumes from twenty minutes to two hours to complete the circulation.

"The *functions* are:—(1) *Mechanical*, as a water-bed and cushion; it serves to protect some parts of the nervous system from shock, to support others, and to aid in maintaining a uniform pressure. (2) *Chemical*, as a protection of the nervous system against infection. The choroid plexus, from which the fluid is largely secreted, acts both as filter and ferment maker. It bars the entrance of certain deleterious substances; and creates antiferments, which destroy and neutralize other ferments. (3) *Distributory;* it carries to the tissues the active principles of the pituitary body. (4) It *transfers* to the blood, in its passage through the different spaces of the nervous system, CO_2 and water, and it *receives* from the blood oxygen and sugar."—(From Hunt's *Diagnostic Symptoms in Nervous Diseases.*)

LYMPH. *Origin:* There are two theories as to the formation of lymph: (1) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (2) That in addition to these, the endothelial cells of the capillaries exercise some influence. *Description:* Lymph is a colorless albuminous fluid, alkaline in reaction, with specific gravity of about 1015, containing lymph corpuscles, and coagulating when drawn from its vessels. *Composition:* Proteins (serum albumin, fibrinogen), sugar, sodium chloride and carbonate, water, urea fat. *Function of lymph:* (1) It conveys nutriment to all cells not directly reached by the blood; (2) in the intestines, it absorbs nutrient material (chiefly fat) and pours it into the blood stream for distribution; (3) it takes certain waste matters to the blood to be later eliminated by the lungs, kidneys, and skin.

The lymphatic system consists of: lymphatic glands, lymph vessels, perivascular lymph spaces, the lymph canalicular system, the pericardial, pleural, peritoneal, and synovial cavities, and the lacteals.

The lymphatic circulation is, strictly speaking, not a circulation at all, since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

The forces concerned in the circulation of the lymph are: (1) The pressure of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

12. *Effect of paralysis of the third cranial nerve.*—Ptosis, external strabismus, dilatation of the pupil, double vision, loss of positive accommodation, the movements of the eye are limited and the eyeball seems to be a little more prominent than normal.

Effect of paralysis of the trigeminus.—Paralysis of the muscles of mastication and mylohyoid and anterior belly of digastric; impairment of hearing, loss of sensation over scalp, face, nose, eye, mouth, teeth, external auditory meatus, and anterior two-thirds of tongue; destructive inflammation of the eyeball; and sometimes atrophy of the muscles of expression.

CHEMISTRY AND TOXICOLOGY.

1. *Metals of the arsenic group.*—These are given differently by various authors. Thus, Witthaus gives arsenic and antimony; Alexander Smith gives arsenic, antimony, and bismuth; Holland gives arsenic, antimony and tin; Simon gives arsenic, antimony, tin, gold, platinum, and molybdenum.

2. *Two official solutions of arsenic.*—Liquor potassii arsenitis, and liquor sodii arsenatis.

3. *Silver nitrate* occurs as colorless, crystalline tablets; in the presence of light and organic matter it becomes grey or black. It is *prepared* by dissolving silver in nitric acid, then evaporating, fusing and recrystallizing. *Symbol* is $AgNO_3$. *Synonyms*, Lunar caustic, lapis infernalis. In the *eye*, a solution of 0.2 to 1 per cent. may be used; in the *throat*, a 2 to 10 per cent. solution may be used.

4. *Colloid chemistry* is the chemistry of colloid substances, or of substances in a colloid state; practically all biochemistry is colloidal chemistry. The building up of the living tissue from the products of absorption, cell life, all the life processes in the human body, the maintenance of water in the tissues, the phenomena incident to fertilization and the early development of the embryo, the process of growth, the nature of muscular contraction, the problems of secretion, edema, inflammation, and nephritis are some of the more important problems whose solution depends on colloidal chemistry.

5. A *calorie* is the amount of heat required to raise one gram of water from 15° C. to 16° C. This is sometimes called a small calorie to distinguish it from the large calorie, which is equal to 1,000 small calories.

The *calorie method of feeding* is the method of arranging a suitable diet by computing the calorie value of the ingredients taken as food. Thus each gram of protein and of carbohydrates is reckoned as furnishing (approximately) 4 calories, and each gram of fat 9 calories.

The calorie requirements of an individual vary according to his work; a man doing light work requires about 2,500 calories a day, and one doing very heavy work (as a lumberman) requires about twice this amount.

6. *Foods are classified:*

I. Inorganic. { Salts. / Water.

II. Organic. { Non-nitrogenous. { Fats. / Carbohydrates. } / Nitrogenous—Proteids. }

Examples of each: *Carbohydrate*, sugar and starches; *Fat*, fat of meat, and butter; *Proteid*, flesh of animals, and white of eggs; *Salt*, sodium chloride, and calcium phosphate.

Carbohydrates.—The name carbohydrate was originally given to the group of compounds found chiefly in vegetables, and containing the elements of carbon hydrogen, and oxygen; the molecule contained six or some multiple of six times the atom of carbon, and hydrogen and oxygen in the proportion to form water. The name is not a good one, and the definition is not accurate; but the term is still used to denote a group of substances which includes the various starches, sugars, and gums, etc. They are generally divided into three groups: monosaccharides, disaccharides, and polysaccharides. In the body they are mainly used for the production of energy and heat.

Cooked starch is acted upon in the mouth by the ptyalin and maltase of the saliva; the former of these enzymes converts the starch into maltose, and the latter turns this into glucose. The intermediary stages are from starch to erythrodextrin, to achroodextrins, to isomaltose, to maltose. In the stomach the action of the ptyalin continues for a time, until the acidity of the gastric juice prevents its further action. In the small intestine, the amylopsin of the pancreatic juice hydrolyzes starch to maltose through the stages of dextrin and isomaltose. The maltose is converted into glucose, which is diffusible through the membrane lining the intestine, and is absorbed and passes into the circulation by way of the portal vein. Glucose is carried to the muscles, where some of it is converted into glycogen and stored (just as it is in the liver); as the needs of the body require it, this glycogen is reconverted into glucose, which is oxidized in the body to carbon dioxide and water (with lactic acid, perhaps, as an intermediary substance). The bacteria in the intestine split the glucose into fatty acids, methane, and carbon dioxide.

7. *Enzymes* are organized ferments produced by living cells; they cause definite chemical changes in certain substances. They are capable of causing change in a large amount of material, and they themselves remain unaltered; they only act in a medium of certain reaction, some in an acid medium, some in an alkaline; for each enzyme there is a certain temperature at which its action is the most energetic; each enzyme acts only on a definite substance; the products of their activity must be removed, or the accumulation of these products will hinder further activity.

8. *Metabolism* is the sum total of all the physical and chemical changes which take place in the living body and which constitute the basis of life. It consists of two forms: (1) *Anabolism*, which is constructive, and consists of the turning of simple molecules into more complex ones; and (2) *Catabolism*, which is destructive and consists of the splitting up of complex molecules into simpler ones.

Nitrogenous equilibrium is that condition which exists when the amount of nitrogen which is taken into the body is exactly balanced by the amount excreted.

9. *The lethal dose of the tincture of aconite* is uncertain, owing to the enormous variations in the strength of the preparation; Riley says "death has been caused by twenty-five drops of the tincture."

The lethal dose of tincture of belladonna is also uncertain; Witthaus reports the case of a man recovering after taking half an ounce of the tincture.

The *lethal dose of the tincture of gelsemium* is given by Riley at "about half a fluid ounce."

10. The result would probably be death.

11. *Symptoms of poisoning by wood alcohol.*—"Gastrointestinal disturbance, abdominal pain, general weakness, nausea, vomiting, vertigo, headache. The symptoms of ordinary alcoholic intoxication supervene, with delirium, restlessness, unconsciousness, collapse, and coma. The pupils are usually dilated and irresponsive; nystagmus may be present. Dyspnea and cyanosis are marked. The temperature is subnormal. There is optic injury, the symptoms of which are bilateral, and consist in scotoma, dimness or total blindness, the pupils are dilated and insensible to light. The loss of vision may start in a few hours, or be delayed several days; it generally becomes complete; subsequently there is some improvement, which in most cases finally relapses into total blindness." (From Sollmann's *Pharmacology.*)

Treatment of poisoning by wood alcohol: Wash out the stomach, and administer a hypodermic of pilocarpine; strychnine is a serviceable tonic, and the iodides are said to benefit the amaurosis. Rectal injections of normal saline solution are useful.

12. *Illuminating gas causes death* by the action of the carbon monoxide, which displaces the oxygen from the hemoglobin, and itself combines with the hemoglobin, making carbon monoxide hemoglobin, which is a very firm and stable compound. *Treatment* consists in artificial respiration; forced inhalation of oxygen, and bleeding, with transfusion of healthy blood.

(*To be continued.*)

BULLETIN OF APPROACHING EXAMINATIONS.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular state.

Fatal Vincent's Angina.—That this affection may exceptionally be fatal is not due to any inherent malignancy, but to chance. Conceivably any affection in the throat could be complicated with a secondary infection of serious character and a Ludwig's angina or similar process develop. Siebenmann has seen death follow profuse hemorrhage from a Vincent ulcer on the base of the tongue in which an artery had been eroded by the disease. The condition had spread despite treatment. This was evidently before the introduction of salvarsan treatment for this affection. The author now uses the latter drug in all cases of Vincent's angina, etc., feeling that the remedy is less risky than the disease. —*Schweizer Medizinische Wochenschrift.*

Original Articles.

A STUDY OF CERTAIN BANDS IN THE RIGHT UPPER ABDOMINAL QUADRANT. ILLUSTRATED BY CASES.*

BY COMMANDER WILLIAM SEAMAN BAINBRIDGE, M.C., U.S. NAVY, R.F.

NEW YORK.

THE object of this paper is twofold. First, to draw attention to some points which have proved of practical value to the writer when operating upon the abdominal viscera. Second, to report, in brief, some selected illustrative cases. The drawings shown were made in the rough when the abdomen was open, and the findings were dictated during operation.

1. The prone position often fails to give the surgeon an exact conception of the conditions present when the abdomen is opened. Early bands and adhesions are often overlooked or their importance not realized. The reverse Trendelenburg will be of aid in arriving at an exact diagnosis. However, this frequently is not sufficient. We must put traction downward on the hollow organs, so as to picture what would be the relations if the erect posture were assumed.

2. It was only after the anatomist placed the body erect, froze it in that position, and made sections, that the exact anatomy of the body cavities and their organs was determined. The roentgenologist early realized that much could be learned by the examination in the upright position. Would not a few dissections made by the abdominal surgeon, with the body upright, be of great value in preparing him for his work? I have found it so myself.

3. Many a small band or adhesion when seen in time, and its significance understood, will, if treated adequately, prevent more serious conditions.

4. "Breaking up of adhesions" is an unfortunate term. In very bad cases that may be all one can do—literally tear these bands and hope that chance will bring those which inevitably reform in places where they will not do as much harm as before. Success sometimes follows such a course, but more often failure. By carefully dividing bands transversely and suturing longitudinally, by flaps of peritoneum or of omentum or skin grafts, many a case of distressing adhesions can be cured.

5. Early adequate attention to bands and adhesions in the right upper abdominal quadrant often makes such operations as cholecystotomy, cholecystectomy, and gastroenterostomy unnecessary.

*Read before American Association of Obstetricians and Gynecologists, at its annual meeting, September, 1919.

6. May it not be possible that by a just estimate of the mechanics of the abdomen and careful attention to the lessons learned, we may better order our lives from the beginning and so often prevent the formation of bands and adhesions, thus obviating their serious sequellæ?

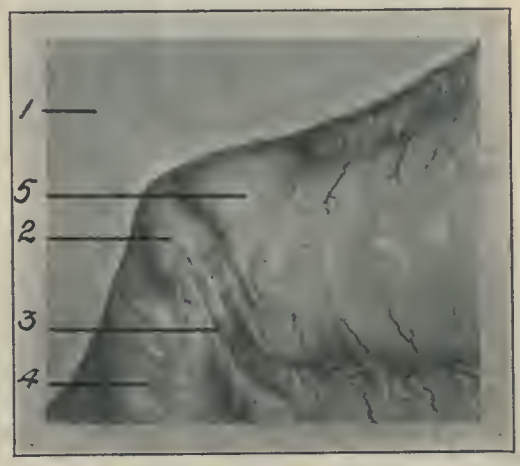

FIG. 1.—1, Liver; 2, Fundus of gall bladder; 3, Bands from gall bladder across duodenum to gastrocolic omentum. Traction on the transverse colon caused these bands to stand out, the gall bladder to be pulled downward, angulating the cystic duct and compressing the duodenum. Practically, the transverse colon was supported by these bands, and the dilatation was proximal to this point; 4, Ascending portion of duodenum distended; 5, Descending portion of duodenum not distended.

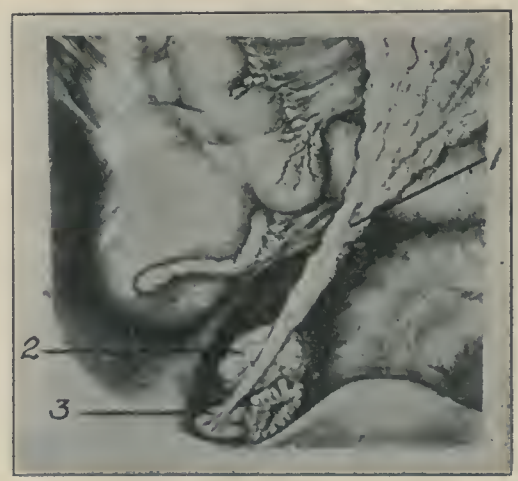

FIG. 2.—1, Omental band; tip of great omentum attached to right ovary and tube; 2, Ovary; 3, Tube.

CASE I.—A. M. Age, 31; female; single. First seen November 29, 1916. *Chief complaint*—"bilious" attacks past two years. At first these came every month, but during the year previous to my seeing her, the average was one a week. Attacks consisted of general malaise, headache, nausea, and vomiting of bile with slightly yellow tint to conjunctiva. No pain. Any

great exercise in the upright posture brought on an attack. Marked constipation. Practically an invalid; unable to work. *Physical Examination.*—Resistance over gall bladder; tenderness over terminal ileum. Poor general condition. *X-ray Examination.*—Dilated ascending colon with ptosis of hepatic flexure. Colonic

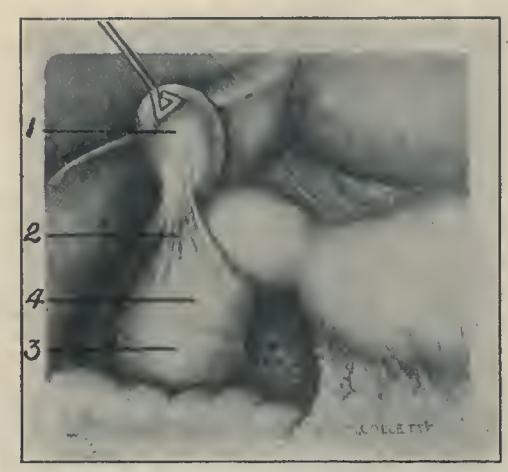

FIG. 3.—1, Gall bladder; 2, Bands, 3, Dilated second portion duodenum; 4, Site of scar of old ulcer. (Picture shown before Railway Surgeons Association, Pennsylvania Lines East of Pittsburgh, at Philadelphia, October, 1916.)

stasis chiefly in ascending colon. *Treatment.*—Six months of best dietetic, medical and physico-therapeutic treatment to avoid operation. Considerable gain in general condition, but attacks persisted. *Operation.*—Polyclinic Hospital, New York, June 5, 1917. Laparotomy. Conditions found as shown in Figs 1 and 2.

The appendix was not diseased, but was removed. Bands relieved in usual way by cutting transversely and carefully suturing longitudinally. On examination after bands were corrected pressure on the gall bladder easily emptied this organ of its contents; no stones found. Attachment of great omentum to right ovary and tube corrected. All raw surfaces covered.

Subsequent History.—Uneventful recovery. Last report September 2, 1919. Teaching or working since September, 1917, continuously. Feels operation has markedly benefited her. Considers herself well. Bowels easily moved by diet.

CASE II.—A. E. Age, 26; male; single. University student. First seen April 6, 1916.

Previous Personal History.—Most of the time for past eight years suffering from hyperchlorhydria. Gastric and abdominal distress with attacks of vomiting and frequent recurrence of symptoms of duodenal ulcer. Marked constipation and loss of flesh. *X*-ray examination in December, 1914, showed some pyloric stenosis. Received medical treatment with little effect. During this treatment was sent to a farm, and in five months lost forty-nine pounds in weight.

Physical Examination.—Tenderness over terminal ileum and duodenum.

X-ray Examination.—Deformity of cap; marked gastric retention, stomach being only half empty at six hours. Descending and horizontal duodenum dilated, suggesting duodenojejunal kink.

Diagnosis.—Old duodenal ulcer and intestinal toxemia.

Operation.—Polyclinic Hospital, New York, April 25, 1916.

Laparotomy.—Conditions found as shown in Fig. 3. Gall bladder adherent to duodenum, with white scar of old duodenal ulcer at base of one of the strong bands. Marked duodenojejunal kink. Cecum dilated. Appendix slightly thickened; removed. Cecum plicated. Bands about gall bladder cut transversely and raw surfaces covered by interrupted longitudinal sutures.

Note.—The retention in the stomach simulating pyloric stenosis was due to a definite duodenojejunal kink.

Subsequent History.—Uneventful recovery. Considered himself perfectly well and entered officers' training camp at Plattsburgh. In the fall of 1917 received a commission in the United States army and was able to go actively into the war.

CASE III.—F. W. Age, 30; female; single. First seen August 7, 1915.

Previous Personal History.—Typhoid fever 1910. Bilious attacks of increasing frequency.

Physical Eaxmination.—Gall bladder tender. Liver slightly enlarged. General enteroptosis.

Treatment.—Diet, medicine, supporting corset and special exercises. Treatment was carried on for a year with the exception of two months when she was placed in reverse Trendelenburg position and given forced feeding and rest régime. Improved, but still complained of attacks of biliousness, with vomiting of bile and gastric discomfort.

X-ray Examination.—General enteroptosis.

Operation—The Lodge, Chautauqua, New York, July 27, 1916.

Laparotomy.—Conditions found as shown in Fig. 4. In addition, marked prolapse of all abdominal viscera; moderate sized duodenojejunal band, kinking the juncture; well developed ileopelvic band. Appendix underhung and adherent to band. Cecum mobile, rotated inward. Ileocecal valve incompetent. Accentuated last kink. Bands cut transversely and sutured longitudinally. Appendix removed. Cecum plicated and anchored. Raw surfaces covered in usual manner.

Note.—When the abdomen was opened and patient was placed in reverse Trendelenburg position, the large intestine became dependent and the band to gall bladder and stomach stood out very clearly, and the kinking of cystic duct was apparent. When the "cholecystocolonic" band was bisected it was very easy to empty the distended gall bladder, which was impossible with a reasonable amount of pressure, before release of the band.

Subsequent History—Patient was given general enteroptic corset and careful régime during convalescence. An automobile ride, soon after leaving hospital, caused pain in small of back for a time. This was relieved by refitting with a new corset and supporting right kidney. In April, 1917, was in excellent condition; gained sixteen pounds in weight; had no more bilious attacks. Last report September 7, 1919. Weighs more than she ever did before. Finished two years work of training for nurse without missing a

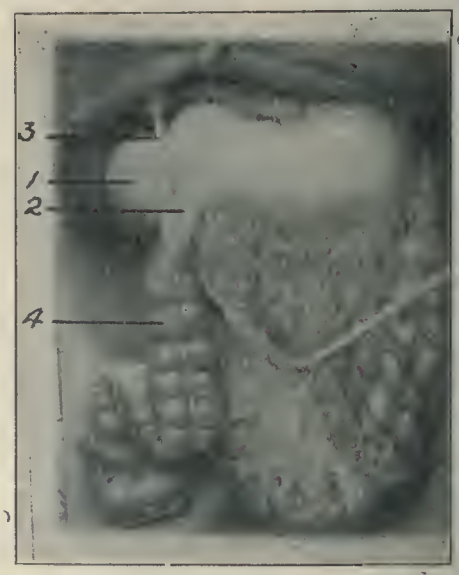

FIG. 4.—1, Dilated duodenum; 2, Band supporting transverse colon; 3, Band from fundus of gall bladder across duodenum coalescing with band from edge of gastrocolic omentum supporting transverse colon; 4, transverse colon.

day. No constipation and no "unpleasant symptoms." Feels better than she ever has in her life.

CASE IV.—S. D. Age, 31; female; married. Referred by Dr. H. W. Schlappi, Fulton, New York. First seen January 12, 1917.

Previous Personal History.—Appendix and right

ovary removed and uterus stitched forward six years ago. Acute attack of tonsillitis in spring of 1916, followed by chills and general yellow tint to skin and conjunctivæ. In November, 1916, had another attack of chills and vomiting of bile, with discomfort in the right hypochondrium; in bed five weeks. She has general abdominal discomfort and nausea. Walks almost with a humpback. After *x*-ray examination recently, previous to seeing me, was told "there were shadows around gall-bladder which were suspicious of gall-bladder trouble."

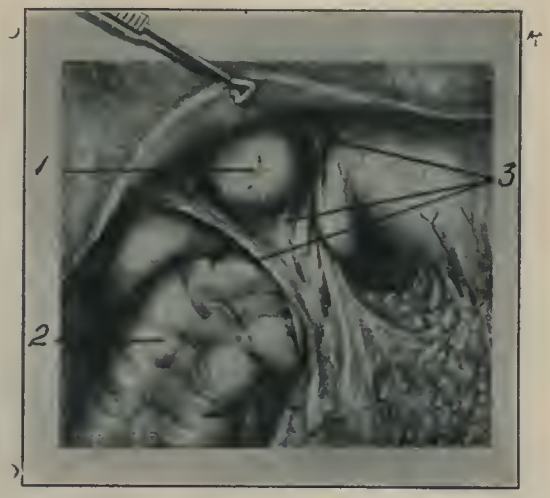

FIG. 5.—1, Distended gall bladder; 2, Hepatic flexure; 3, Bands constricting duodenum.

Physical Examination.—Tenderness over gall bladder, liver and terminal ileum. General enteroptosis. Right kidney floating. Some secondary anaemia. Practically a chronic, nervous, dyspeptic invalid.

X-ray Examination.—Nothing pathological in or about gall-bladder (this contrary to the diagnosis made by the first roentgenologist); pelvic adhesions with some compression of the terminal ileum.

Operation.—Polyclinic Hospital, New York, January 25, 1917.

Laparotomy.—Conditions found as shown in Fig. 5. Great omentum tightly adherent to scar of previous laparotomy wound, which extended from umbilicus to symphysis. Attachment of great omentum fixed stomach and transverse colon to abdominal wall. This easily explains the humpback attitude the patient assumed when standing, which started soon after the previous laparotomy several years ago, and which had become more marked of late. Stomach enteroptic. Pylorus normal. Y-shaped band attached to under surface of liver, in center of which was gall bladder, distended, but containing no stones. Band was very strong; its upper attachment consisted of three forks —one to right of gall bladder, one to gall bladder and one to left of gall bladder. This went almost to gastrohepatic omentum, across transverse colon. Distinct duodenojejunal kink. No adhesions around old appendix stump. Cecum dilated. Pericolic bands along cecum and ascending colon. Right tube and ovary absent. Uterus retroverted and retroflexed. Last kink of pelvic colon markedly angulated. Bands and adhesions were treated in the usual manner, restoring, as far as possible, normal continuity of hollow viscera. Uterus anchored forward by Johnson-Willis operation. Duodenojejunal band stretched, as it was found unnecessary to bisect it.

Subsequent History.—Convalescence prolonged but uneventful. Last report, July, 1919. Old symptoms entirely relieved. Good general condition. Walks perfectly well. Able to do her own work.

CASE V.—A. Z. Age, 35; male; married. Referred by Dr. John A. Breglia, New York. First seen March 8, 1917.

Previous Personal History.—Recurrent mild attacks of appendicitis with constipation, and at times distress in the right hypochondrium.

Examination.—Tenderness over appendicular region; high placed appendix.

Diagnosis.—Intestinal toxemia with relapsing appendicitis.

Operation.—Polyclinic Hospital, New York, March 9, 1917.

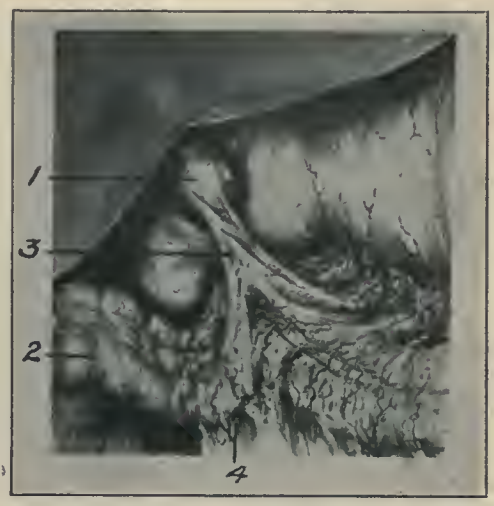

FIG. 6.—1, Gall bladder; 2, Hepatic flexure; 3, Y-band with two arms downward supporting transverse colon across duodenum by attachment to fundus of gall bladder; 4, Thickened edge of great omentum.

Laparotomy.—Conditions found as shown in Figs. 6 and 7.

Appendix found chronically diseased with some adhesions. Beginning diverticulum of cecum. Distinct constriction of transverse colon, even in supine posture, a band from gall-bladder, extending from base to fundus, across duodenum to gastrocolic omentum, folding up omentum which was tightly adherent to gall bladder. Appendix removed; cecum plicated; bands freed in usual manner. Raw surfaces turned in.

Note—This might easily have been taken for a case of mild relapsing appendicitis, and the removal of appendix considered sufficient. The importance of not always accepting the appendix as the cause of all the trouble, and the wisdom of making a careful abdominal examination is clearly demonstrated in this case.

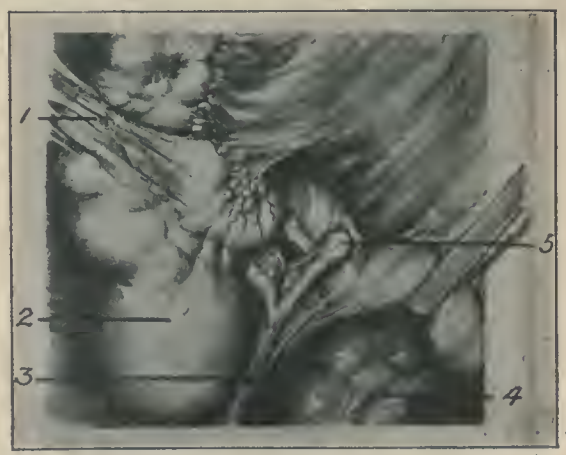

FIG. 7.—1, Pericolic bands, so-called "Jackson membrane," attempting to hold up rotating mobile cecum; 2, Diverticulum of cecum; 3, Ileopelvic band with appendix attached; 4, Pelvic colon; 5, Bulbous end of appendix.

Subsequent History.—Convalescence uneventful. Last report August 4, 1919. Patient looking and feeling perfectly well. The physician who referred the case to me states that the man has not had a sick day since the operation.

Case VI.—H. K. Age, 25; female; single. First seen April 10, 1916.

Previous Personal History.—Compelled to give up college work and was drifting toward chronic invalidism. In January, 1914, had attack of appendicitis. In bed a week; no operation. Six weeks later had another attack. On March 18, 1914, had appendix removed and uterus stitched forward. Markedly constipated. Since operation has felt well for only three or four months, and dropped from 137 to 114 pounds in weight. Has abdominal discomfort, especially referable to epigastrium most of time. Frequent eructations of gas. At times nausea and occasional vomiting.

Fig. 8.—1, Gall bladder; 2, Band at base of gall bladder and along cystic duct across duodenum; 3, Band from liver to cystic duct, tending with gall bladder in dependent position, to rotate cystic duct; 4, Transverse colon; 5, Band extending across pylorus. (Picture shown before Railway Surgeons' Association, Pennsylvania Lines East of Pittsburgh, at Philadelphia, October, 1916.)

Physical Examination.—Some psoriasis. Lumps in upper and outer quadrant of both breasts. Considerable abdominal gaseous distension. Thoroughly toxic. This was such a marked case of chronic intestinal stasis that *x*-ray examination was deemed an unnecessary expense.

Operation.—Polyclinic Hospital, New York, April 14, 1916.

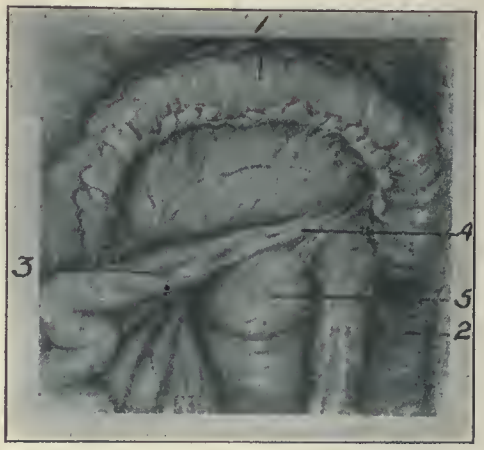

Fig. 9.—Transverse colon held up, exposing region of duodenojejunal obstruction. 1, Transverse colon; 2, Descending colon; 3, Collapsed jejunum; 4, Bands about termination of duodenum; 5, End of dilated doudenum, showing marked distention; effort being made to empty stomach by pressure on gastric organ which markedly dilated duodenum to point of duodenojejunal kink.

Laparotomy.—Conditions found as shown in Figs. 8, 9, 10 and 11.

Stomach prolapsed so that lesser curvature lay below umbilicus. Pylorus and duodenum greatly dilated. A strong band of adhesions attached above to gall-bladder—from near apex of fundus to gastrohepatic omentum—crossed duodenum and extended over pylorus at one point. Main part of band went downwards to prolapsed transverse colon. Lying in prone position on operating table real significance of band was not apparent until traction of colon was made, simulating conditions in standing position. Then a marked indenting of duodenum—almost obstruction—by this band from gall-bladder to colon, was clearly demonstrated. A very strong band which rotated gut outward and caused considerable obstruction, went across ascending colon just below hepatic flexure. Small ileopelvic band. Cecum very mobile and greatly enlarged. Sigmoid redundant with accentuated last kink. Bands treated in usual manner; cecum enfolded. All raw surfaces covered.

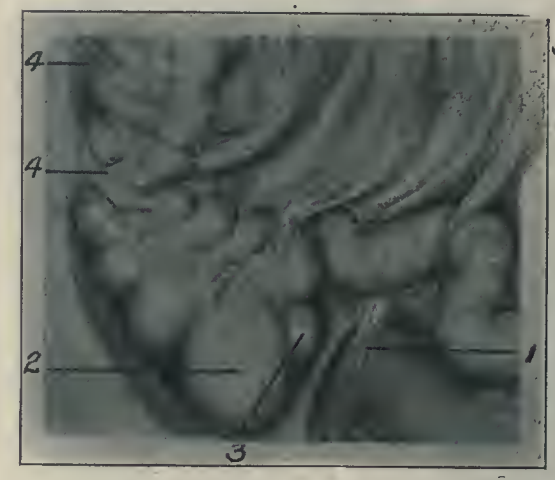

Fig. 10.—1, Small ileopelvic band; 2, Diverticulum; 3, Stump of appendix; 4, Ileopelvic bands. The juncture of cecum with ascending colon forms a point of obstruction when mobile cecum tends, when full, to rotate from above downwards and from without inwards.

Subsequent History.—Convalescence uneventful. Last report July 8, 1919. Perfect condition. Lumps in breast disappeared. Patient states she could not wish for better health.

In the aforementioned cases, many symptoms were referable to the right upper abdominal quadrant and those consulted had considered the probability or certainty of the presence of gallstones. None were found, and there seemed no need of removing a gall-bladder which was not, apparently, diseased. All these cases were treated by the least amount of surgical interference which the pathology seemed to demand.

Fig. 11.—1, Pelvic colon; 2, Accentuation of last kink.

Allow many of these bands to remain and the patient to gain in strength, the points of obstruction become more acute, the toxemia continues indefinitely, and the inevitable added pathology often means conditions requiring far more surgery.

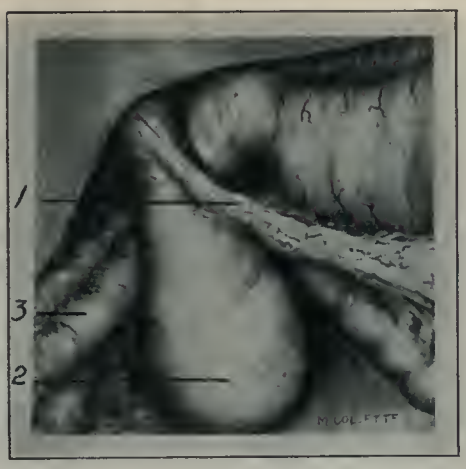

Fig. 12.—1, Band twisting outlet of gall bladder; 2, Distended gall bladder; 3, Hepatic flexure.

The following three cases illustrate this point.

Case VII.—E. R. Age, 45; female, single. Referred by Dr. Wm. Van Valzah Hayes, New York City. First seen December 11, 1915.

Previous Personal History.—Typical of intestinal toxemia with what was called "mild gall stone attacks"; some hemorrhoids.

Physical Examination.—Large, distended gall bladder, extending practically to umbilicus.

X-ray Examination—Large distended cecum with first degree patency of the ileo-cecal valve. The cecum is so dilated that the effort of defecation does not empty it.

Operation.—Polyclinic Hospital, New York, December 12, 1916.

Laparotomy.—Conditions found as shown in Fig. 12. Large, distended gall-bladder. Angulation of cystic duct near base by strong band across duodenum to gastrocolic omentum. This band not only angulated duct but rotated gall-bladder and kinked large gut when traction was made on transverse colon, as in upright posture. Gall bladder removed; no stones. Bands corrected. All raw surfaces covered. Condition of patient was such that it was judged wise to attend only to right upper quadrant.

Pathological Report.—Chronic inflammation of gall sac.

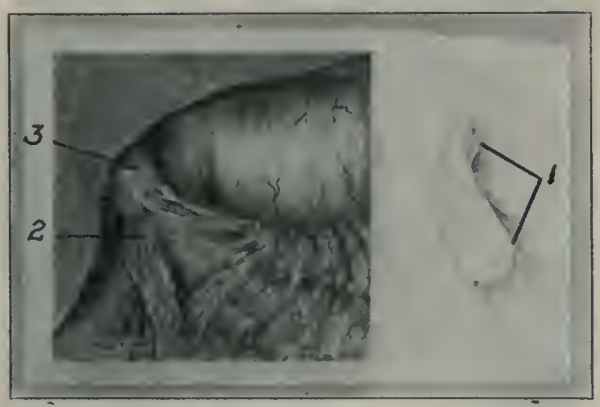

Fig. 13.—1, Gall bladder with seventy-five stones; kinked at base by band over duodenum to region of cystic duct. Band attached to mass of adhesions and situated around fundus of gall bladder; 2, Mass of adhesions; 3, Fundus of gall bladder. (The mass of adhesions around the gall bladder was distinct, although attached to the single band at the base of cystic duct.)

Subsequent History—In February, 1917, after an uneventful convalescence returned to work seemingly perfectly well. Lost sight of at end of 1917 when she was reported by Dr. Hayes as in excellent condition.

Case VIII.—C. F. Age, 60; female; married. Referred by Dr. C. P. Faller, Carlisle, Pa. First seen April 24, 1917.

Previous Personal History.—For seven years off and on discomfort in right upper abdominal quadrant. Marked constipation. Hemorrhoids. Intestinal toxemia. Typical gall stone attack December, 1916.

Physical Examination.—Distinct tenderness over gall bladder and descending duodenum. Some tenderness over ileum and last kink. Anaemic.

X-ray Examination.—"Pathological gall bladder with pericholecystitic adhesions, the probable presence of gall stones, and a tender, partially fixed, stiffened cecum from adhesions which may be the result of a chronic appendicitis."

Operation.—Polyclinic Hospital, New York, May 8, 1917.

Laparotomy.—Conditions found as shown in Fig. 13. Appendix kinked, chronically inflamed and underhung, causing ileal stasis. Great omentum attached to right lateral wall, suspending gut. Gastrocolic omentum near pylorus and lower part of pyloric portion of stomach on greater curvature was attached by a strong band from fundus of gall bladder across duodenum to transverse colon. An extension downward toward common bile duct of thin white fibers caused angulation at junction of cystic duct with common bile duct, making it difficult for gall bladder to empty itself normally. Seventy-five stones of varying sizes found in the gall-bladder. Before opening organ four stones were milked back from common bile duct; one large stone had to be broken between fingers. Appendix removed. Bands treated in usual manner. Gall bladder opened and stones removed. Closure as usual.

Subsequent History.—Convalescence uneventful. Last report September 8, 1919. No recurrence of attacks; has gained twenty-two pounds. Marked constipation relieved. In excellent condition.

Note.—The gall-bladder was not particularly thickened, and the condition of patient was such that it was deemed best only to remove the stones and drain the organ. According to a classification accepted by some, we would consider two types of bands being present in upper quadrant—the smaller, evolutionary, and the mass, inflammatory.

Case IX.—A. B., age, 47; female; widow. First seen March 1, 1917.

Previous Personal History.—Constipation and "indigestion" since child was born, twenty-four years ago—supposedly bilious attacks or gallstones. Severe attacks at first came every six months, stopped for a time, and then came on once every two or three years. Jaundice eighteen years ago. Operation for rectal fistula fifteen years ago; drained for a year; cured after second operation. Recently discovered a lump in left breast.

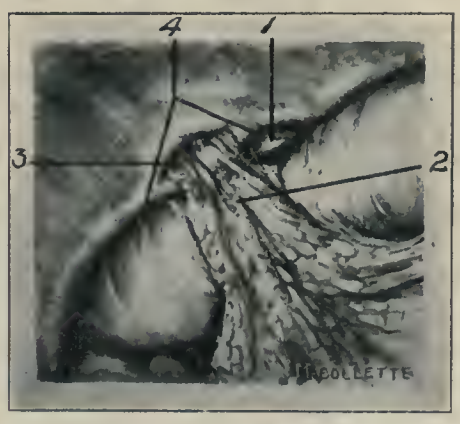

Fig. 14.—1, Gall bladder; 2, Mass of adhesions; 3, Scar nodule very suspicious of malignancy; 4, Small section of liver removed with nodule.

Physical Examination.—Lumpy condition of upper and outer quadrant of breasts, particularly left one. Tenderness over gall bladder and appendix. Cystocele and rectocele.

X-Ray Examination.—Practically negative.

Operation.—Polyclinic Hospital, New York, March 27, 1917. Laparotomy. Condition in gall bladder region as shown in drawing XIV.

When the abdomen was opened a small nodular mass at edge of liver, close to gall bladder, was discovered. This was situated where a strong band of adhesions found attachment above, extending over duodenum down to transverse colon—hepatocolic band. The possibility that this was malignant and the presence of so much needing attention elsewhere in abdominal cavity made operator decide to remove this section of liver for examination after relieving all other pathology, except in right upper quadrant. Accordingly, section of liver as shown in Fig. 14 removed, and iodine gut sutures used to close gap and stop hemorrhage. Other conditions found and corrected: Terminal ileum fixed by ileopelvic band. Appendix thickened and under inner margin of dilated cecum. Accentuation of last kink, fastening about two inches of terminal colon to left lateral wall. Upper four inches of ascending colon adherent to corresponding length of first portion of transverse colon. All bands carefully cut and raw surfaces covered in usual way. Appendix removed. Cecocolonic plication with anchoring of gut.

Pathological Report.—Scar tissue at edge of liver—chronic inflammation, apparently beginning to undergo degenerative changes.

Second Operation.—Polyclinic Hospital, New York, April 13, 1917. Matters attended to at operation, March 27, 1917, satisfactory. Great omentum adherent over liver scar and about site where small drainage tube had been employed for few days after previous operation. Omental adhesion relieved and gall bladder exposed. Many adhesions divided. Duodenum at one point markedly constricted by bands. Released. Gall sac with mass of stones and inflammatory tissue around two calculi, which had ulcerated through gall bladder, removed en masse. Drainage. Closure in usual manner.

Subsequent History.—Convalescence uneventful. Saw patient July 14, 1919. Breasts normal. States she is perfectly well as far as she knows.

United States Naval Hospital, New York, N. Y.

OBSERVATIONS AFTER SEVERE GUNSHOT FRACTURES OF THE LONG BONES.

By C. WINFIELD PERKINS, M.D.,

NEW YORK.

LATE ROENTGENOLOGIST BASE HOSPITALS 8 AND 69, A. E. F., AND U. S. GENERAL HOSPITAL 8, OTISVILLE, N. Y.

It is not the purpose of this paper to infringe in any way whatsoever upon the field and activities of either the internist or the surgeon in diagnosis and treatment; however, I have always maintained, and I think justly, that the mental flexibility of the Roentgenologist must be as broad as either one of them; for without adequate medical and surgical knowledge he is unable to cope with the medical problems of the day, as portrayed on the *x*-ray plate or screen.

Too high praise cannot be given the Thomas arm and leg splint in its essential uses both on the field and in Base Hospital treatment. The ease with which wounded men with smashed fractures could be handled with a minimum amount of pain in the *x*-ray laboratory was a dominant observation. With the use of this splint, pain was not only diminished or prevented, but bleeding was checked and the immobilization of the fragments prevented further injury to the soft tissues and bones and subsequent spreading of sepsis. Another observation which often presented itself was the value of the trained hands of a physician of experience, in the personal handling of patients upon the *x*-ray exposure table. Such work should not be left to one without medical training.

Fig. 1.—For description of the illustrations see page 601.

Sir Anthony Bowlby has recently stated that many things have been taught us in the treatment and the handling of fractures in this War. In following

Fig. 2.

up patients I have frequently observed, along with my colleagues, that the loss of bone substance to the extent of 1 to 2 inches may be replaced without appreciable shortening of the limb; that is, if suit-

able treatment with splints and the proper extension is applied. *X*-ray examination has proven many times that it is not necessary to approximate bone ends in order to obtain complete union, providing proper alignment and position are obtained and

Fig. 3.

maintained with apparatus designed after the Thomas splint. Bone will practically always fill in the intervening space, if sufficient time is allowed. This same osteogenesis will also follow a severe

Fig. 4.

osteomyelitis. In fact, bone will replace itself even while infection remains in the wound.

The question of bone removal after severe gunshot injuries was not settled when the Armistice occurred; however, there is no doubt that the removal of all fragments which might necrose will hasten wound healing, while on the other hand removal of fragments delays union of the fracture. It therefore appears that many of the bone frag-

Fig. 5.

ments, in spite of infection, aid materially in the reconstruction process. The others become necrosed and slough out. Evidently those pieces of bone with portions of the periosteum remaining become part of the new bone, fusing with it, and act as the patient's own bone graft. Frequent *x*-ray examinations have driven home this observation.

The lessons of War Surgery are becoming more apparent daily in their applicability and usefulness in the industrial field of work, where thousands of men are employed in the industries and frequent accidents occur that simulate gunshot injuries. Much has been taught the surgeon by the frequent following of such cases by means of the *x*-ray examination. I believe that industrial surgery will receive a new impetus, as the result of the experiences in the War, in the treatment of severe crushed bone injuries with infection.

Fractures as a class, according to many authorities, require more skill and judgment in treatment than the ordinary laparotomy; the latter operation has its dramatic side, but I believe it does not call for the responsibility and ingenuity in treatment that a difficult fracture does. In civil life two varieties of fracture are noted, the displaced and the nondisplaced variety, the latter of which needs little adjustment. Practically all war fractures are of the compound comminuted type. Every effort should be made to save the bone fragments. Sequestra and devitalized fragments can be recognized by fre-

quent Roentgenological examination. Such examinations were always made of severe comminuted fractures for the purpose of viewing the position of the fragments and the progress of union, as well as to determine the presence or absence of osteomye-

Fig. 6.

litis. The observation of callus, sequestra, gas gangrene, and pus pockets was the special field of the *x*-ray. Proper treatment was therefore given according to the findings.

Amputations were less frequent in this war than in previous wars. If the vascular supply was intact wonderful results were obtained by conservative treatment, even when the bones were horribly smashed; therefore many observers came to the conclusion that primary amputation, especially of the hip, was so uniformly fatal that it had better not be done.

Fractures of the femur, especially of the upper third and into the hip joint, were frequently observed in our Base Section. Many of the wounds showed the explosive effect of bullets not only on the femur itself but on the associate bones in the hip-joint region, some of which were frightfully comminuted. Many of the patients came under observation 2 to 4 months after being wounded, having been collected from various sectors and finally centralized at the large Base in Savenay. The *x*-ray examinations often showed severe osteomyelitis on the road to recovery or healed. Severe fractures were often noted healed or on the road to recovery, with shell fragments and machine gun bullets *in situ*, and all external evidences of infection removed. Experience had taught the surgeons that an old osteomyelitis may be awakened if an effort is made to remove the foreign body. A conservative attitude was always maintained in such cases.

It was surprising to note how often after a severe splitting injury resulting from a bullet or shrapnel impact, many fragments will appear to be intermingled with pieces of a foreign body, illustrating the explosive effect of a bullet, yet the bones will heal with good union and functional results, although the foreign bodies remain in situ. I remember very well the case of an officer who received a machine-bullet wound in the upper third of the femur. The entrance and exit bullet wounds in the muscle and skin were of the ordinary punctured character, but upon examination with the *x*-ray the bone was seen to be shattered into what appeared to be a hundred pieces; still the patient's thigh healed after several months, with a good result.

The difficulties to be overcome in operating an overseas *x*-ray laboratory were many. Irregularities of electric supply were ever present and were very annoying to say the least. Adverse climatic conditions coupled with insufficient water and heat supply, aside from cramped quarters to work in, made it ofttimes seem impossible to develop so many as one to two hundred exposures per day. Naturally under such adverse conditions, the technical results obtained in the laboratories at home under normal surroundings could not be duplicated.

In conclusion it must not be forgotten that we were dealing with a single class of patients, the

Fig. 7.

pick of the country for physical vigor, trained young men selected for their health and physical prowess. Many times even though stricken with grave and apparently mortal injuries, they would show a re-

siliency and "come back" not seen in the average individual. This factor must always be considered.

DESCRIPTION OF THE ILLUSTRATIONS.

FIG. 1.—Illustrates osteogenesis and fusing of the bone fragments after the sequestra have been thrown

FIG. 8.

off or removed. The callus formation and bone reconstruction process are clearly depicted between the distant bone ends. Note the perfect bone alignment which was found to be necessary for perfect filling in of the space between the shafts. There is a small fragment of a foreign body in the upper part, which was too small to be removed, and the attempt at its removal would cause more damage than good to the patient. This photograph illustrates firm union with practically little or no shortening of the limb. Time, about four months after being wounded.

FIG. 2.—Shows a compound comminuted fracture of the lower third of the femur with outward and backward displacement. This is held in position by the Thomas splint with traction. Note the bony bridge of callus between the two distant bone ends; the shady and not so dense portion between the fragments. There is present a small fragment of shrapnel with numerous other tiny portions too small to be removed. There still remains a moderate degree of osteomyelitis in the upper portion of the lower fragment. This will clear away.

FIG. 3.—Demonstrates a definite dense bridging in of two distant bone ends held in position and alignment by means of the Thomas apparatus. There is firm union in this case, with very little if any osteomyelitis remaining. Note the numerous pieces of foreign bodies too small to be taken out in the lower part of the shaft. This patient will undoubtedly have good union with little or no shortening of the limb.

FIG 4.—Shows a compound comminuted fracture of the upper third of the femur, in good alignment and position. Distance of bone fragments about one and one-half inches. A few tiny bullet fragments are present in the wound. Note how all the fragments are fused or absorbed. The interesting feature in this case is the bony bridge on the inner side which simulates a bone graft it may be called Nature's own graft. The pointed ends of the approximating shafts show erosion of an old osteomyelitis, which has cleared away to a certain extent. The prognosis of such a case, as to firm union and very little shortening of the femur, is very good.

FIG. 5.—Shows a compound comminuted gunshot fracture of the lower third of the femur well on the road to recovery. There was good alignment and position with firm union at the time the Roentgenograph was taken. This was originally a severe shattered fracture, but nearly all the fragments are now reunited. The periosteal bone bridges on both the outer and inner sides are firmly united with the upper and lower portions. In the center the arrows point to a sequestrum, in a pocket, which was removed. A good result can be anticipated in such a case with practically no shortening of the limb.

FIG. 6.—Shows a fractured femur similar to that in Fig. 5. There was good alignment and position with firm union. The periosteal bone bridges on both the outer and inner surfaces are firm and dense, which denotes excellent bony union. These bony splints hold the upper and lower fragments with great firmness. The arrows point toward a sequestrum and also a focus of osteomyelitis which still remains in the medulla. This is from all practical purposes walled off and only necessitates removal of the sequestrum and subsequent healing will follow. This Roentgenogram was taken about four months after injury. A few very small foreign bodies still remain in the wound.

FIG. 9.

FIG. 7.—Illustrates a severely shattered fracture of the middle of the femur due to the impact of a soft bullet or shell fragment. There are numerous flattened-out foreign bodies throughout the wound. They are too thin and scattered to be removed. Callus de-

posits are taking place, and the original fragments are being fused to form a new shaft. The upper and lower fragments are in good alignment.

FIG. 8.—A healed fracture of the compound comminuted type. The line of fracture is just below the neck and the greater tronchanter. The soldier presented good function with practically no shortening. The *x*-ray appearance of the healed part is dense and normal throughout. There is very little deformity, and the alignment is excellent. There are a number of thin foreign bodies imbedded in the bone which are doing no harm. Osteomyelitis in the bone has disappeared entirely.

FIG. 10.

FIG. 9.—This is the most remarkable linear split fracture that I have seen or heard of being recorded. It may be called a "rail split fracture." It was probably received while the soldier was lying in the direction of the bullet. The femur was split throughout its whole length by the course of the bullet. There is still present osteomyelitis in the bone, but the injury at this time, four months after, had every evidence of the patient recovering eventually. The fracture is in a Thomas splint.

FIG. 10.—Shows a very severe comminuted fracture of the lower two-thirds of the humerus. There is still osteomyelitis present. The fragments are retained, and

FIG. 11.

FIG. 12.

FIG. 13.

FIG. 14.

in spite of the osteomyelitis are fusing together. The arm is retained in a plaster cast. There is considerable deformity present. As this *x*-ray picture was taken about four months after the injury, there was hope at the time that the arm could be saved. It was impossible to follow this case as in many others, for the patients

FIG. 15.

were as soon as possible evacuated to the United States.

FIG. 11.—Another severely comminuted fracture similar to that shown in Feg. 10, except that it is in the lower tibia and fibula. All the fragments in this case were retained and are now fusing. At the time the patient had fairly good union with little deformity. The effect of shrapnel impact is distinctly demonstrated in this case. A few tiny foreign bodies are still in the wound. A moderate degree of osteomyelitis is present but in spite of this the patient is now well on the road to recovery.

FIG. 12.—The arrows point to a bridge of bone about three inches long in the middle of the radius, uniting the upper and lower portions. The upper third of the ulna also shows an oblique fracture. This case is specially interesting for it demonstrates the new shaft of bone reforming when the mid-portion of the radius had been shot away. The radiograph was taken four months after the receipt of the injury. The whole arm is in a plaster cast.

FIG. 13.—Shows a fracture of the upper third of the femur healed; there is practically no deformity, only slight outward displacement of the upper fragment. The interesting feature about this patient is the imbedded machine gun bullet in the region of the greater trochanter and neck. There is no osteomyelitis surrounding the bullet, therefore no effort was made to remove the projectile, as an old osteomyelitis might be awakened with such a procedure. The soldier was not suffering any inconvenience from it, and was not aware of its presence until his hip was *x*-rayed. The picture was taken several months after the receipt of the injury. He had received treatment for the fracture in a forward area, where, I believe, the *x*-ray was not available at the time.

FIG. 14.—A severe fracture of the upper third of the humerus; from the surgical neck, three to four inches of bone down the shaft had been shot away. The bone ends have been kept in perfect alignment as seen by the splint in position. There is good bridging in on the

outer and inner sides with a new periosteal wall, the medulla shows the fine granular type of callus present. All osteomyelitis has disappeared and it is only a question of time when the bone becomes dense enough so that the splint can be removed, and the patient will have an excellent shaft of the humerus as a result. The

FIG. 16.

case very clearly demonstrates the fact observed in the War, that if bone fragments are kept in alignment and position the intervening space from two to three inches may be filled in, forming a new shaft, with practically no shortening, as an end result.

FIG 15.—Nonunion of the middle of the shaft of the femur. There is, however, an attempt at union as seen by the callus on the inner side and scattered callus between the bone ends. The dark area on the outer side represents a pocket of pus. The bone ends are serrated, showing oseomyelitis present with erosion. This case demonstrates more the unusual result, than the usual as seen in the majority of long bone fractures. However, there is hope that with the treatment and time union will be obtained, as the upper and lower portions of the bone appears to be quite healthy. *A bone graft in this case would be useless, as osteomyelitis is present.*

FIG. 16.—This is a compound comminuted fracture of the whole upper third of the femur, the result of the explosive effect of a bullet. The shaft has been shattered into what seems hundreds of small fragments. The entrance and exit of the bullet were of the ordinary punctured type of wound. This Roentgenograph was taken four months after the injury and shows well the fusion of fragments and osteogenesis. There are numerous small portions of metal in and around the bones, but they are too small to warrant an attempt at removal. The wound was healed when this photograph was taken. The patient, an officer, was evacuated for the United States a few days following, having at the time good function of the limb. The ring of the Thomas splint is seen in the upper portion of the photograph.

180 WEST FIFTY-NINTH STREET.

REPORT OF A CASE OF BILOCULAR UTERUS WITH CARCINOMA IN THE LEFT HORN.*

BY O. C. MELSON, M.D.,

ROCHESTER, MINN.

FELLOW IN SURGERY ON THE MAYO FOUNDATION, UNIVERSITY OF MINNESOTA.

CASE 59169.—Mrs. G. R., aged 50, was first examined at the Mayo Clinic in September, 1911. She had been married 25 years, and had never been pregnant. During the year prior to her coming to the clinic her menstruation had been irregular, at intervals of from two to three months, the last period occurring six months before. Except for typhoid at the age of 19 there was no history of illness until her present complaint.

When the patient presented herself for examination she complained chiefly of constant aching in the left leg, knee, and thigh, and of swelling of the entire extremity. This had occurred at intervals for two years, varying in severity. A feeling of fullness and distress with gas was present after eating. She thought her abdomen was enlarged generally and had known definitely of an enlargement in the left iliac fossa for two or three years.

Physical examination except of the pelvis was practically negative. There was a soft systolic cardiac murmur. A tender mass could be palpated in the left iliac fossa. The superficial veins of both legs were varicosed. Bimanual examination disclosed the presence of an irregular, hard, movable mass, apparently attached to the uterus, which practically filled the pelvis. A diagnosis of pelvic tumor, most likely uterine fibroids, was made, and a subtotal abdominal hysterectomy was advised. The patient was not able to remain for the operation, but she returned five years later, October, 1916. She had passed the climacteric at 52 and had had no vaginal bleeding until three weeks before her return, when she noticed a small amount of blood; the bleeding had recurred every day. The growth of the tumor had been slow but progressive and the patient had experienced varying types of pain in the pelvis and thighs, at times aching, at others, very sharp, and occasionally, of a bearing down nature. She also complained of a frequent desire to urinate.

Physical examination produced no new findings, but the mass in the pelvis appeared less freely movable. A diagnosis of uterine fibroids was again made and a total hysterectomy was advised.

The patient was not operated on until November 7, 1917, at which time Dr. W. J. Mayo performed a total abdominal hysterectomy, with removal of both ovaries and tubes. At operation the tumor mass was found to be fibroids of the uterus extending well up to the umbilicus. The entire uterus, both tubes, and ovaries were buried in a mass of adhesions involving the sigmoid. A diagnosis of multiple fibroids of the uterus, which in view of the recent bleeding were regarded as suspicious of malignancy, was made. In removing the uterus it was found to have two cervices. The vagina also was double.

In the pathological laboratory the specimen was found to be a double uterus (uterus bilocularis) complete, with the exception of the tubes (Fig. 1). Three large fibroids, measuring from 8 cm. to 12 cm. in diameter, obliterated the normal contour of the uterus; one was situated on the right, one on the left, and one between the two portions of the uterus. Two normal appearing cervices were separated by a well defined septum.

Upon section of the gross specimen two distinct uterine cavities were encountered, separated by a septum varying in thickness from 1 cm. to 3 cm. The right cavity was lined throughout by slightly hypertrophic endometrium. In the left horn of the uterus was a tumor 2 cm. in diameter, with the gross appearance of carcinoma of the fundus of the uterus without ulceration (Fig. 2). It was well

*From the Section on Surgical Pathology.

circumscribed and appeared to be composed of multiple papilliferous formations of the endometrium. The tumor when cut appeared to involve chiefly the mucosa, but the microscopic section showed that the uterine wall penetrated almost to the serous coat (Figs. 3 and 4).

Wertheim[6] describe similar cases. Biehl[1], in 1893, demonstrated a specimen of a malignant adenoma in a bicornate uterus. Penrose, in 1894, reported a case of carcinoma of the fundus with extension of the bladder and vaginal wall. The condition was found to be inoperable on exploration. Necropsy

FIG. 1.—Photograph of gross specimen showing two cervices and the right uterine cavity opened through the anterior uterine wall. The left cervical canal is partially visible.

FIG. 2.—Uterus bilocularis with four myomas. The uterine cavities are laid open, exposing a carcinoma in the fundus of the left body.

In most of the cases of anomalous uterus reported thus far the lesion has been in the cervix and the anomaly a bicornate uterus. Zweifel[7], Orthman[4], and

revealed a bilocular uterus with two cervices and two vaginas. Buist and Valentine[2], in 1914, reported a similar case in which there was glandular

involvement, and reviewed the literature on the association of carcinoma with double uterus. Perhaps the only case of a real double uterus in association with a carcinoma was reported by Czwerwenka[3], in 1904. The fundi were separted and there were

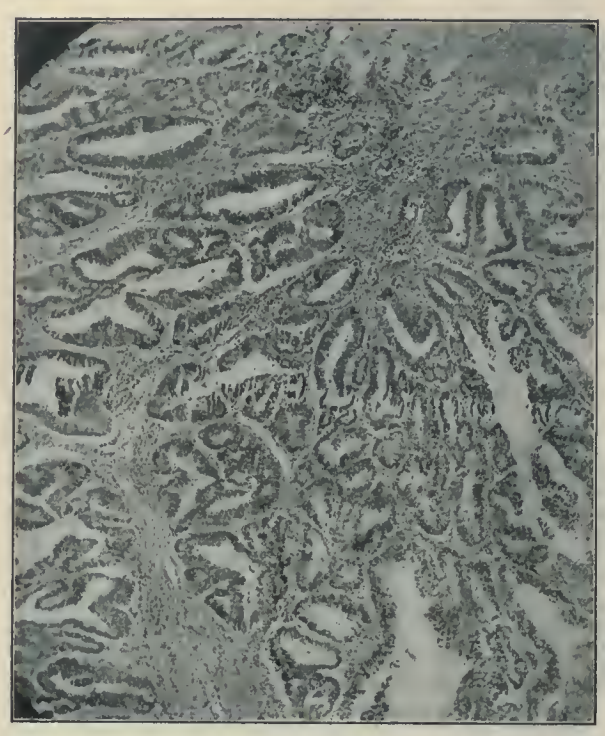

FIG. 3.—Low-power photomicrograph of carcinoma. The area shown was situated just beneath the serosa; it shows the extent to which the carcinoma has invaded the uterine musculature. (X 50.)

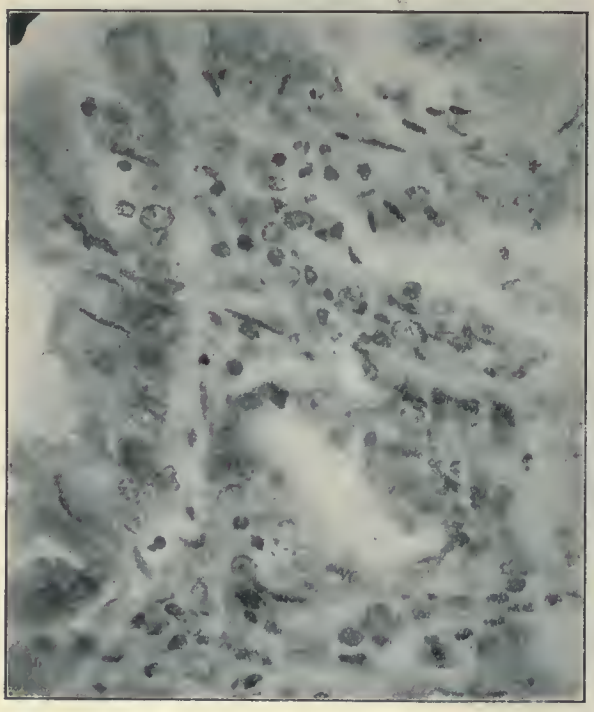

FIG. 4.—High-power photomicrograph showing the typical carcinomatous characteristics of the cells lining the uterine gland acini. (X 500.)

two cervices and two vaginas. The carcinoma was situated in the left fundus. The other cases demonstrate only partial formation of the anomaly.

DIFFERENTIAL DIAGNOSIS BETWEEN THE PAINS OF TABES DORSALIS AND THOSE OF FOCAL INFECTION.

REPORT OF A CASE PREVIOUSLY TREATED UNSUCCESSFULLY FOR SYPHILIS, WITH COMPLETE RELIEF OF SYMPTOMS FOLLOWING EXTRACTION OF ABSCESSED TEETH.

BY ALBERT M. CRANCE, M.D.,

BAY CITY, MICH.

FIRST ASSISTANT IN THE DEPARTMENT OF DIAGNOSIS, JONES CLINIC.

CASE NO. A-577.—An American, male, railroad examiner, aged 40, entered with a complaint of "rope sensation around the waist, and pains in all parts of the body."

Family history: Negative as to similar conditions, carcinoma, or tuberculosis. He had been married sixteen years. He had one daughter, 14 years of age, who was in good health. His wife had had one miscarriage.

Previous history: Twenty-four years ago the patient had had diphtheria. Twenty years ago he had had a "soft chancre," which lasted but three days. It was treated with calomel powder. Eighteen years ago he had an attack of gonorrhea. He had had no previous operations or injuries.

Habits: Coffee, 2 cups; tea, 1 cup daily. He had formerly smoked cigars excessively, but had not used tobacco for the past year.

Present illness: Nine years ago the patient began having "lightning pains." These started in the knees and gradually became general. He had also had a "rope sensation" around the waist.

Previous treatment: Nothing had ever stopped the intense pains from which he suffered severely. Within the past nine years he had been treated for syphilis, having taken several courses of salvarsan, mercury injections, and inunctions, but with no relief of his symptoms. Several Wassermann tests had always been negative.

Physical Examination.—The patient was tall and thin. His height was 6 feet 1 inch; weight 160 pounds. His complexion was moderately pale. Scalp examination was negative. The nose and ears were apparently normal.

Teeth: There were present a moderate degree of pyorrhea, several fillings, and crowns. Dental *x*-ray examination (Figs. 1 and 2) showed the upper left central and lateral incisors, the upper left first bicuspid, and upper right central incisor to be abscessed. There was a massive abscess at the root of the lower right first molar. The lower left second molar showed rarefaction at its root, due to infection traveling downward from a pyorrhea pocket. The lower left third molar was devitalized.

Tonsils, moderate in size. There was a very slight chronic pharyngitis present. The submaxillary lymph

nodes were prominent on both sides. The heart presented normal physical signs; systolic blood pressure, 120; diastolic pressure, 80; pulse, 86. The lungs were apparently normal except for a few râles on both sides. The abdomen, genitourinary organs, and rectum revealed nothing abnormal. There were two small, hard

Fig. 1.—A-577; *x*-ray views of upper teeth showing advanced pyorrhea, abscesses at the roots of the left central and lateral incisors, upper left first bicuspid, and upper right central incisors. These teeth were extracted.

lymph nodes in the right inguinal region. There was a small red cicatrix over the right scapular region. The pupils were equal; sluggish reaction to light. The patellar reflexes were somewhat diminished. Romberg's sign was slightly positive. There was a slight suggestion of an ataxic gait.

The résumé on the day of examination was set down as follows: Focal infection; possibly a cured case of syphilis.

Laboratory Reports.—Urine, acid; specific gravity, 1020; negative for albumin, sugar, and casts. Blood, hemoglobin, 85 per cent.; leucocytes, 12,000; Wassermann test, negative. The spinal fluid Wassermann and a Nonne test were both previously found to be negative; six small lymphocytes in the spinal fluid count.

Treatment.—The abscessed teeth were all extracted and the patient has undergone rigid prophylactic treatment for pyorrhea.

Results.—The patient returned in three weeks completely relieved of the pains he has had for the past nine years. It is now two months since the abscessed teeth were extracted. The patient states that he is

Fig. 2.—A-577; *x*-ray views of lower teeth showing the massive abscess at the root of the right first molar. The left second molar shows rarefaction at its root. The lower left third molar is devitalized. These teeth were also extracted. Relief was most pronounced after extraction of the right first molar.

steadily gaining strength, his pains and "rope sensation about the waist" having entirely disappeared.

This case presents many interesting features. First of all, the necessity of a differential diagnosis is something of unusual occurrence. It is perfectly possible that this patient might have had syphilis, and just as probable that he did not have it. Assuming that he did have syphilis, he has had such intense antisyphilitic treatment that it seems improbable that his present symptoms would have been due to that disease. Also, for the past nine years, in spite of the intense treatment, he had not improved, but on the contrary he had gradually become worse.

The physical findings were very suggestive of tabes dorsalis, and yet no sign was at all positive. The pupils reacted sluggishly to light, but it would be incorrect to call them Argyll-Robertson pupils. Romberg's sign was merely suggested, and not strongly positive as we should expect nine years after the onset of tabes. The patellar reflexes were diminished, but not absent. The gait was suggestive of the ataxic type, but was by no means positive.

There was a strong possibility that he might have had syphilis, and that the condition was arrested by the intensive treatment; however, his present symptoms could easily have been due to another cause, and the most probable one was focal infection. The fact that the "rope sensation around the waist" disappeared following the above treatment is sufficient to prove that syphilis alone was not the cause of it.

Conclusion.—I have presented this case to illustrate the importance of a more careful consideration of focal infection. This patient's condition had several times previously been diagnosed as tabes dorsalis, and on none of the occasions had focal infection been considered as a possibility in its etiology.

A PRELIMINARY REPORT ON THE USE OF A NEW ARSENICAL COMPOUND IN THE TREATMENT OF SYPHILIS: "MON-ARSONE."

By COMMANDER B. L. WRIGHT, M.C., U.S. NAVY,
LIEUTENANT L. A. KENNELL, M.C., U.S. NAVY,
AND
L. M. HUSSEY.

Not being satisfied with our results in the treatment of syphilis with arsphenamine and neoarsphenamine we began a search for a new arsenical compound embracing certain qualifications that would render it superior to both of the older preparations, in regard to safety, ease of administration, and parasitotropic action.

With this in view we determined that the new compound must be less toxic than arsphenamine or neoarsphenamine, perfectly soluble in water, and capable of intravenous administration in concentrated solutions without the use of apparatus other than a suitable syringe; that it should, if possible, contain more arsenic than the older compounds, and that it must be stable enough to resist the decomposing action of time, extremes of temperature, and sterilization by autoclaving or boiling, and that this stability must be maintained as permanently as possible when the compound was placed in solution.

By July, 1919, one of us (H) had deveolped and perfected what appeared to be the desired compound, viz., disodium monoethylarsone, CH_3CH_2AsO

$(NaO)_2$ in which the arsenic content is 38 per cent. as compared with arsphenamine 31 per cent. and neoarsphenamine 20 per cent. For brevity this compound has been called Mon-arsone.

Mon-arsone is an aliphatic compound of arsenic, and the aliphatic compounds were chosen for investigation because of our persuasion that the cyclic compounds, of which arsphenamine and neoarsphenamine are examples, owe a part of their instability and toxicity to the linkage of arsenic with the benzene radical. It is well known that the aliphatic compounds are more stable and it was our belief that we could find one in which this stability would not interfere with parasitotrophic activity.

Mon-arsone was finally chosen as a compound of simple, stable nature, containing an ethyl instead of the customary methyl groups of the aliphatic arsenic compounds heretofore proposed in Medicine. By the introduction of the ethyl group we believed that not only would toxicity be reduced, but that surprising differences in chemical and pharmacological activity would be observed, in accordance with the fact that in homologous series of compounds, wide differences are observed between the methyl and ethyl compounds, although otherwise such series maintain their homologous characteristics.

Mon-arsone is a pure white, somewhat crystalline powder. In air it deliquesces with the absorption of moisture but does not oxidize. It has no odor, a salty taste, and is extremely soluble in cold or hot water. Its solution is colorless and when properly stoppered is perfectly stable and may be kept without decomposition for long periods of time. These solutions may be boiled or autoclaved without alteration.

With varying amounts of water it forms a series of semicrystalline hydrates, which are decomposed, yielding the anhydrous salt, by desiccation in a vacuum.

Determination of Toxicity and Dosage.—To determine its toxicity experiments were conducted upon thirty-two healthy rabbits, all of which were injected finally with an amount of the compound equivalent to four grams based upon a man of a hundred and fifty pounds weight and reduced proportionately to the body weights of the animals used.

Not a single death or observable reaction occurred in any of the animals, which were later killed, and at necropsy there was in no case any evidence of pathological conditions found, especial attention being paid to the kidneys, heart, liver, and meninges.

Examination of the rabbits' urine failed to show the presence of albumin or red blood cells.

Following this animal experimentation, two of us submitted to intravenous injections of the compound, also to subcutaneous injection, the later to determine its corrosive action on tissue. Subcutaneously there was but a slight sensation of burning pain which lasted only a few minutes, and did not produce any local inflammatory reaction.

By these means and through volunteers (syphilitics) who submitted themselves for treatment, our main efforts have been directed toward establishing the proper dosage.

At the present time we have been using 2.4 grams in 12 c.c. of sterile water at blood temperature once every seven days. In no instance have we observed the semblance of a reaction or arsenic intolerance.

Mode of Administration.—In each case, just before the injection and twenty-four hours later the urine was examined and no evidence of pathological changes in the kidneys noted.

Blood counts were made just prior to and five hours following the injection and showed no change in the count except in the total white in which an increase of 2,000 to 3,000 invariably occurred and remained for about thirty-six hours. At no time was hemolysis of the red blood cells introduced into the solutions.

We prepared and administered the compound as follows: A solution containing 200 milligrams in each c.c. of distilled water was filtered and sterilized either by boiling or autoclaving.

The dosage desired was then drawn up into an allglass graduated syringe, using a platinum-iridium needle of 22 or 23 gauge. The solution was previously warmed to blood temperature. It was then injected slowly into the vein, usually the median basilic.

It is probable that in females the dose should be smaller than the one we advise for males, viz., from 2 to 2.4 grams.

In our studies we have not supplemented the arsenical treatment by intercurrent administration of mercury, and the results noted below are entirely due to the compound under discussion.

Treatment of Specific Infections.—To date (December 24, 1919) we have treated 20 cases. In but few of these has the maximum dose been primarily administered. In all of the cases the treatment extended over a period that was not more than two and a half months at a maximum.

Eleven presented negative Wassermanns, two were two plus, two were one plus, and five still remain four plus. In all but one case, however, the clinical symptoms have entirely disappeared.

As it was our purpose in the beginning to establish the optimum therapeutic dose, which was necessary before we could give especial attention to the therapeutic properties of mon-arsone, all these cases were given their initial treatment with doses that were less than two (2) grams. Our first dose was half a gram which was increased by two-tenths of a gram increments weekly. The maximum amount of Mon-Arsone given any one patient during the course of treatment was fourteen grams. The minimum amount given any one patient before the Wassermann became negative was one and four-tenths grams.

The average number of injections given each man in the twenty cases was 4.7 two-gram doses.

Of the eleven cases presenting negative Wassermanns the average number of injections required was 3.5 two-gram doses.

It seems probable, in those cases in which the Wassermann is still positive, that through the administration of small initial doses, gradually increased in the experiments to determine dosage, the patients became Wassermann-fast. This has been borne out by the fact that when these patients were taken off the mon-arsone treatment, during

which time they had received no mercury, and placed upon a mercury treatment they showed rapid reduction of the Wassermanns to negative. As it is the purpose of this paper to discuss only the action of mon-arsone alone, the treatment of a series of patients with combined mon-arsone and mercury will be presented in a subsequent communication.

The abstract of the case records of the following six cases will demonstrate the therapeutic value of mon-arsone unaided by mercury, in the treatment of syphilis.

CASE I.—C. H. F. Untreated syphilis of fifteen years' standing which had been repeatedly diagnosed and treated as non-specific arthritis deformans. Coming under our observation September 11, 1919, when the blood showed a four plus Wassermann, he received two injections of 0.6 and 0.8 gram respectively of mon-arsone, following which the Wassermann became negative and has remained so to date. All symptoms disappeared and from a bed-fast patient he is now performing his full duties.

CASE II.—R. L. Exposed September 1, 1919, initial lesion September 18. On October 2 a four plus Wassermann. A total of 13.8 grams of mon-arsone in nine injections was administered to this patient, by which time the Wassermann was negative and all clinical symptoms had disappeared.

CASE III.—E. H. E. No history of primary or secondary lesions. Reported complaining of a growth on the external condyle of the left humerus, seriously interfering with joint action. *X*-ray diagnosis was "either sarcoma or gumma." On October 1, 1919, Wassermann four plus. He received a total of twelve grams of mon-arsone in six injections, when the Wassermann became negative. During the period of this treatment he received fifteen grains of potassium iodide *t.i.d.* At the time the Wassermann became negative the growth had about disappeared and he had almost complete motion in the elbow joint.

CASE IV.—J. R. H. Initial lesion September 26. Chancre on coronal sulcus. Dark field examination negative to spirochetes. Wassermann negative on Sept. 29, October 6 and 16, becoming four plus on November 3, 1919. Beginning with November 6 he received 3.6 grams of mon-arsone in two injections, the Wassermann becoming negative on November 11. At this time there was no symptomatic evidence of syphilis.

CASE V.—C. D. Initial lesion June 15, 1919. First seen on October 11, 1919, at which time he had a macular eruption on belly and chest. Blood gave a four plus Wassermann. Beginning October 16 he received a total of 4.8 grams of mon-arsone in three injections. The week following the Wassermann was negative and all symptoms of syphilis had disappeared.

CASE VI.—W. E. Exposed August 1, 1919. First seen September 11, 1919, presenting a large indurated ulcer on the penis. Three dark field examinations at four-day intervals were negative for spirochetes. On September 22 the blood presented a four plus Wassermann. Beginning September 25 he received a total of 3.4 grams of mon-arsone in four injections. Chancre promptly healed following the first injection. A week following the fourth injection the blood presented a negative Wassermann. No secondary symptoms.

Conclusions.—From our investigations we believe we have demonstrated that the standard we laid down for an ideal arsenical compound in the beginning of this paper has been fulfilled in Mon-Arsone. It is decidedly less toxic than the arsphenamine compounds as evidenced by the fact that 0.6 of a gram of arsphenamine, containing 186 milligrams of arsenic (2.8 grains), the maximum dose of this drug, frequently produces distressing and sometimes fatal reactions, while mon-arsone, in 2.4 gram doses, containing 1.064 gram arsenic (16.7 grains) has failed to produce a reaction or a toxic symptom of any description.

Mon-arsone is perfectly soluble in small amounts of hot or cold water and may be administered in solutions in which each c.c. represents 200 milligrams of the dissolved solid without the slightest danger. Its singular property of having no hemolytic action upon the red blood corpuscles in this heavy concentration makes such a concentration unobjectionable.

It requires no special apparatus for its administration.

It contains approximately seven per cent. more arsenic than arsphenamine.

The solution of mon-arsone are so stable that they completely resist oxidation or decomposition when boiled or subjected to the higher temperatures and pressures of the autoclave.

While mon-arsone is designed to be administered intravenously, accidental extravasation from the vein need not be feared, for from our premiditated subcutaneous injections of this drug and from several accidental leakages from out the vein no untoward results have been noticed.

These manifest advantages make it possible for any well qualified physician to administer this treatment as a routine office or bedside procedure, and render it possible for the naval and army surgeon to have this desired therapeutic agent at his command at all times whether at sea or in the field.

Mon-arsone has passed all the requirements demanded for arsenicals by the Public Health Service, having successfully met the established tests prescribed, and made in the Hygienic Laboratory, Washington, D. C.

A NOTE ON CASES OF SUDDEN CANITIES IN HISTORY.*

BY CHARLES GREENE CUMSTON, M.D.,

GENEVA, SWITZERLAND.

PRIVAT DOCENT OF THE HISTORY OF MEDICINE AT THE UNIVERSITY OF GENEVA; A VICE-PRESIDENT OF THE HISTORICAL SECTION, ROYAL SOCIETY OF MEDICINE OF LONDON, ETC.

THE cases of sudden emotional canities which history has transmitted to us are derived from the most varied sources; the majority of them have been furnished by historic annals, gazettes and collections of curious and extraordinary occurrences. They only penetrated the medical world at a later date, and even the oldest accounts have simply passed down to generation from generation, each writer quoting them without himself investigating the source, and imparting to them under all possible reserve before consigning them to science. They have consequently been handed down with that character of indecision, that absence of detail which are invariably to be found in accounts of acts insufficiently observed and incompletely described.

The historian seized upon them before the physician, because he saw in them curious and unexplained phenomena, capable, for this very reason, of interesting and astonishing the reader. The sage, being in the impossibility of verifying them, could only accept them with a very limited credence. My absolute ignorance of the modern pathogenesis of canities in general, as well as the present status of the subject, prevent me from offering any remarks,

*Read before the Medical Society of Geneva, Dec. 3, 1919.

and I most willingly leave to those among you who are competent in the matter of dermatological pathology the task of bringing the subject up to date.

One of the oldest documents relating to sudden emotional canities is the following, extracted from the *Histoires admirables et mémorables de nostre temps"* (*Chronique d'Arras,* 1604). (It is difficult to translate the old French texts into English; therefore, indulgence must be given to the writer in his rendering, but the accuracy of the English version he will vouch for.)

"Several persons who were imprisoned for crime, and believing that they were in danger for their lives, in a single night, from black, red, or blond haired that they were as people are in the fullness of maturity, all became as white as aged persons."

"A young gentleman of the court of Emperor Charles V, becoming in love with a young lady, went so far that, partly from love, partly by force, he plucked her flower of virginity: which having been discovered, he was imprisoned especially because the act was committed on the premises of the Emperor, and was condemned to lose his head; then having been informed in the evening that his life would be ended on the following day, this very same night was for him so fearful and had such an effect upon him, that the next morning, leaving the gaol to appear before the judge of justice in order to hear the death sentence, nobody recognized him, not even the Emperor, because fright had so changed him that instead of having as yesterday a fine red color, blond hair, pleasant eyes, a face to be looked at (with pleasure), he had become like an unearthed corpse and had the hair and beard as white as a septuagenarian and appeared more like a hanged man than a living one. The Emperor suspecting that some fraud had been practised and that this was some other criminal who had been substituted in the place of the gentleman (who had not attained the age of twenty-eight years), suddenly ordered an inquiry to be made in order to discover how came this wonderful and sudden change and to consider the affair carefully; then looking upon the poor frightened criminal, the desire of just vengeance changed to that of pity, and when his mind had returned from the depths of thought, said to him: 'I pardon thee for thy crime,' and ordered that he be released, saying that he had already been (the prisoner) sufficiently chastized for his crime without leaving his head (on the scaffold)."

"Another young Spanish gentleman, by the name Jacques Orsario, of illustrious family, became in love with a maiden of the court, having made a plot with her, climbed a tree in the king's garden and hid there awaiting his time. Thereupon, a little dog appeared, which by his barking caused the discovery of the personage, who was made to come down (from the tree) to go to prison, in order to make good by the loss of his head this mistake, regarded as capital (offense) in this country for divers reasons. The sentence of death given him frightened him so that the next morning, having become as white as an old man of eighty, no one knew him. Thus he obtained pardon from the King of Spain, ancestor of Charles the Fifth."

"A hunter searching for the young of a sparrow-hawk on a high rock, feeling the rope which helped him to descend was giving way, had such fright that suddenly his hair became entirely white."

The work of Schenkius, *Observationum medicurum rariorum libri vii,* contains quite a number of instances of sudden emotional canities. I here append some extracts.

Hadrianus Junius (*Comment. de Coma, c. 10*) states that he had seen shipwrecked persons, who, having lost all hope of being saved, had become white in a short time. He also says that he had seen the hunters of Cappadocia climb from rock to rock and become white (the hair) when the rope holding them began to give way or broke. He likewise relates the case of Osario, an extract of which I have given above, from the *Chroniques d'Arras.*

Vines (*in Praefat, in somn. Scipionis*) relates the case of a certain Jacobus Orsorinus, a young man one, thrown in prison, became completely white in one night. This is undoubtedly the same Osario already referred to above with an orthographic error.

Scaliger (*Exercit, 312, ad subtilit, Cardani*) says that Francisco Gonzague ordered that one of his relatives, suspected of conjugation, should be confined in the tower of the imperial gates, in order that he might be put through an examination (questioning) or be put to torture. When this was announced to the guilty person, he became quite white. Moved by this prodigy, Gonzague pardoned him.

Aventinus (*Annalim Boiorum liber vii*) tells the following: Louis of Bavaria, on the Rhine, was repressing the towns in revolt. He learned that his wife was unfaithful; he returned in great haste, caused her to be thrown from the top of a tower and married another. In the night he had a vision which revealed to him his error; all his hair turned white. From remorse he founded a monastery in Bavaria, which he named Furstfeld.

Crantz (*lib. ix, Metrop., c. 47*) refers to a certain monk, by name Ubipertus, who, being found too young by the sovereign pontiff for occupying the chair of a bishopric, *made himself white in the night* (italics are mine), and thus forced the assent of the Pope. This observation is very obscure, as the text says that he "made himself" white.

Nicolas Florent (*Serm. 7, trac. 6, sum. 3, c. 24*) says that he had seen the son of one Mathai Lippi of Scarparia and a shoemaker of the market town of St. Laurent, Zechium by name, both of whom whitened from fright.

Speronus Speronius (*Dialog. de partu mulierum*) states that a noble of Papavium, to whom it was announced in the evening that he would lose his head the following day, turned white in the night.

In Mart, *a Delrio e societate,* the writer says that his father, when ill, heard the doctors say he was lost; he was at the time fifteen years of age. From the fear of death his hair suddenly whitened.

The following is extracted from Lorry: *De morbo cutaneo.* "Pleni sunt auctorum libri exemplorum canitiei præ fimore intra breve spatium accersitæ. Famosa est historia illa ab Hadriano Junio reversita nobilis Hispani Didæi qui, cum ob furtivos amores illicitos practaque claustri regii jura, capitali supplicio plectendus esset, ita canitiem unde quaque contraxit, ut Fernandus rex, misericordia motus, ipsi caput remiserit. Simile habet

exemplum Julius Scaliger; et in nostra historia viro nobili de Saint-Vallier cujus ingratiam Diana Pictavis ejus folia regios concubitus passa est, eadem improvisa canities adventasse legitur. Aut nil memorandum magis quam quod aulicis narrabat æternæ memoriæ rex noster Henricus IV, se scilicet mœrore et metu incubuisse per xxiv horas, linienæ illus Bartholomæanæ tempore, eoque exacto, hanc et barbæ et capillorum partem fuisse in canitiem conversam, quam ostentabat."

The two examples, of the Spaniard Didœus, who indulged in fleeting amours in a royal cloister, and of Saint-Vallier, whose daughter could not obtain his pardon until she had served as the king's mistress, are good examples of the historic tales of canities. The third, that of Henry IV, is an instance of partial canities.

Guarini, of Verona, one of the restorers of the classical Greek learning in Italy, was suddenly attacked by canities at the instant that he was told of the loss of his Greek manuscripts at sea, which he had been at great pains to collect at Constantinople.

Concerning Ludovic Sporza, called the Moor, it is said that his hair became suddenly white during the night following the day when he fell into the power of his mortal enemy, Louis XII.

In the night of July 3, 1534, which preceded his execution, Thomas Morus, Chancellor of England, became white, both in beard and hair.

It has been stated that Marie-Antoinette grew white during the night preceding her execution, but this is inexact. The Goncourt brothers say in their *Histoire de Marie-Antoinette, Paris*, 1858, that the Queen had perfectly white hair when she was beheaded, but that she had become gray at the time of the death of the King.

A certain Nicolaus Micholdius d'Indevelda, one day asked the learned Schenkius to explain a case of sudden canities that he had heard related. The learned doctor compared the hair to the leaves of trees or to vine leaves which are fed by the juices of the soil, which are united to the tree which bears them, although they are not inherent parts. Dryness and the winds may strike them with decay, dry them, and cause them to fall, without involving the vitality of the trunk, which is no longer able to nourish them.

Daniel Semertus said the same in 1676: "Si enim ex nubula, vel aere, aut vento vitioso arbores affluente, foliorum color mutatur et ea enarescunt ipsa arbore et partibus aliis salvis menetibus, non impossibile est, capillorum etiam, ut corporis nostri partium ignobilissimum, colorem vel spiritu eos subito pervadente mutari."

We no longer live in the days of hypotheses of such poetical nature as those emitted by the good Schenk and Semertus. In modern times sudden emotional canities has been denied by many writers. Pincus, for instance, says that a man walking by a river saw a child fall into the water; he threw himself in after the child to save it. At the instant that he caught it he recognized his own offspring, and when he reappeared his hair and beard were gray. Pincus concludes, however, that the man had dyed his hair and beard, and that the water dissolved the dye.

3, Rue Bellot.

SOME PERSONAL VIEWS OF BRONCHIAL ASTHMA.

By EDWIN ZUGSMITH, M.D.,

PITTSBURGH, PA.

The writer feels that in the following brief and informal paper there will be presented a viewpoint sufficiently at variance with the accepted ideas on asthma to prove of interest. These views upon the subject of bronchial asthma are the outcome of experience and apply only to the so-called idiopathic or bronchial asthma, to the exclusion of other forms of dyspnea, such as cardiac and renal asthma and likewise the so-called pollen asthma.

Asthma may be defined as a non-febrile disease manifesting itself chiefly by severe dyspnea with expiratory difficulty, cough, and expectoration. It is essentially chronic, although its manifestations vary greatly from time to time and in their relative prominence.

It is marked by paroxysms which under ordinary circumstances last but a short time—a few hours to a day or two—but which under aggravated conditions may continue for weeks and even months without any relief worthy of the name.

The onset of the attack is insidious and mild, but in a very short time the symptoms increase progressively to a severe degree, the patient is compelled to sit, preferably leaning forward; there develops the greatest difficulty in breathing, there is a frequent hard cough without expectoration, and the chest is a bedlam of coarse noises which can be heard at a distance. After a while the cough becomes productive and the mucus thrown off is more or less tinged with blood—an evidence of the intense engorgement of the bronchial tubes.

The temperature does not rise, the pulse does not increase much in rate and is of low pressure. The skeletal muscles are called to the aid of the patient in breathing, the neck enlarges therefore and the patients often complain of severe pains in the throat and chest.

No characteristic pathology has been found and therefore asthma has usually been placed among the functional disorders. Of course the bronchitis is present, but there is nothing to distinguish it from bronchitis occurring under other circumstances. In long-standing cases the bronchial tree is thickened. There is no connection between asthma and tuberculosis or syphilis.

Much thought has been given for a long time to the explanation of the production of the phenomena constituting asthma, and of recent years infinite industry has been applied to the solution of its problems. The previous neurotic theory has been pretty generally replaced by the newer and more attractive and, it may be added, more satisfying anaphylactic theory. The evidence showing the necessity of assuming anaphylaxis as the fundamental in explaining the existence of the form of asthma under discussion is not convincing.

Asthma is unquestionably a manifestation of toxemia, but whether it results from a direct action of the poisonous material, such as we find, for example, in the effect of digitalis on the heart, or of strychnine on the central nervous system, or whether it acts primarily by sensitizing the in-

dividual, cannot be said. Only the isolation of the toxic substance and observation of its effects can solve that question.

Two metabolic studies made upon one patient gave different results, a third study on a second patient agreed with neither, so that it would seem that no metabolic disturbance gross enough to be determined by present methods lies at the bottom of the trouble.

Nasal polyps, deflected septa, hypertrophied turbinates are removed or corrected without any decided influence upon the course of the disease. Pus about sinuses, and more recently about the teeth, gums, and tonsils have each and all had to bear the odium of etiology, but these conditions too are corrected without result.

Climatic influences are supposed to be responsible for asthma, but when one finds the same patients with outbreaks coming irrespective of season and irrespective of location with reference to sea level or to temperature, one cannot but feel skeptical about such factors.

The favorite attitude at present is to look upon bronchial asthma as the result of one of two anaphylactic agents either bacterial or alimentary. And treatment has been in accordance. A vaccine is made from the predominating bacterium found in the sputum and injected in gradually increasing amounts at selected intervals. The vaccine is changed as the predominating organism changes.

The alimentary form is determined by scratching the skin and rubbing into the abrasions dried protein extracts of foods and noting those producing redness and swelling as the offending agents. Remarkable results have been reported by men who have used these as the basis of treatment.

However, these methods sometimes fail and it becomes necessary to look further for means of aid, and the search has led the writer to this conclusion, namely, that the large bowel is a prominent place in which originates a poison that causes asthma. It is not claimed as the only place of origin but there is convincing evidence that it is one that must be reckoned with. To one on the lookout for it there will be surprise at the number of asthmatics with colitis as indicated by mucus in the stools. He will be struck likewise by the frequency of constipation and rarely of diarrhea with retention in these patients. He will be astounded from time to time if he will observe the magical and instantaneous effect of a well administered enema, even during the severest attack.

In asthma it is of primary and essential importance to be most solicitous concerning the bowels. They must be kept open and care must be taken to know that the lower bowel has emptied itself completely. It will not serve the purposes of the asthmatic to have a fractional movement, and he must be taught to look after the evacuations with the same persistency that the diabetic is urged to use in regard to his diet.

Observation over a lengthy period has shown that it is advantageous to use castor oil routinely every six or seven days; laxatives are used daily where required, and at the onset of an attack patients are instructed to take an enema.

Under such treatment it is not necessary to restrict the patient to a meat-free diet, since it is likely that a meat diet exerts its evil effect through its constipating tendency.

No reference has been made to the use of drugs, since the writer has nothing to add to the common knowledge on that subject. Potassium iodide still remains the most effective medicinal remedial agent. Beyond its effect upon the bronchitis itself, the writer would suggest the possibility of its exerting some action within the intestine.

8030 Jenkins Arcade.

Medicolegal Notes.

City's Power to Establish and Receive Benefactions for Tuberculosis Hospital.—The Louisiana Supreme Court, in a suit to enjoin the City of New Orleans from establishing and maintaining a tuberculosis hospital, holds that such a hospital, 600 feet removed from a residence, is not a menace to the people living in the residence. The evidence was held to show that a well-kept tuberculosis hospital is not a menace to the health of the people living in its vicinity, and it was presumed that the hospital would be well kept. The medical evidence, detailed in the court's opinion, was held to show that the hospital was an imperative necessity. "This necessity," the court said, "while not creating an enforceable legal duty, does create a municipal duty, and a clear one at that. The regular way of discharging this duty would be, of course, by means of the establishment and maintenance of a municipally owned and controlled hospital. But suppose the city is financially unable to do that; is this deplorable condition of things to be left to continue and daily grow worse? It would be strange, it seems to us, if any city, confronted by a situation of that kind and yet unable from lack of funds to cope with it by means of a municipally owned and controlled instrumentality, should be simply helpless, because destitute of power to adopt some other means ready to hand such as a contract like the one involved in this case." The contract in question was with a benefactress, who donates $153,000 for the construction of the building and an endowment fund of $150,000 for the maintenance of the hospital, whereby the city agrees to perpetually dedicate to a perpetual board of trustees a site for the hospital and perpetually appropriate a certain sum annually for its maintenance, but is to be given a yearly report by the board. Probably no city in the United States has broader powers than the city of New Orleans. By section 6 of its charter it is expressly authorized "to adopt such ordinances and regulations as shall be necessary or expedient for the protection of health and to prevent the spread of disease." By Section I, par. g. "The city shall also have all powers, privileges and functions which, by or pursuant to the Constitution of this State, have been or could be granted to or exercised by any city." It is held that in view of these provisions the contract was not void as granting the city's funds and property in violation of Constitution Act 58, since the establishment of the hospital is a municipal duty and, though the contract did not so provide, its apparent purpose was to render services free of charge to the poor and needy.—Le Bourgeois v. City of New Orleans (La.), 82 So. 268.

Keeping Duplicate Prescriptions of Habit-Forming Drugs.—A practising physician in Tennessee prescribed morphine for a habitual user, after personally attending the patient, but kept no copy or duplicate of the prescription. He was convicted of distributing, dispensing, and prescribing morphine without keeping a duplicate of the prescription. The Tennessee Supreme Court has reversed the judgment and dismissed the case, for the following reasons. The Tennessee act of 1913 bearing upon the subject is as follows: "Physicians who shall dispense or distribute any of the aforesaid drugs provided by this act shall keep a duplicate of all prescriptions issued by them for a term of two years." The court holds that all physicians are not included within this provision, but only those who dispense or distribute the drugs. The defendant did not dispense or distribute morphine, therefore he did not violate the act.—Friedman v. State (Tenn.), 213 S. W. 418.

MEDICAL RECORD.

POLYMORPHISM OF ENCEPHALITIS LETHARGICA.

EVERY month brings new evidence of the polymorphism of this disease. At a recent session of the Paris Academy of Medicine reported in the *Progrès Médical* for February 28, 1920, xlviii, 9, Marie describes the meningeal reactions recently seen in six cases of the malady. The number of lymphocytes in a cubic mm. of spinal fluid varied from 8 to 24, and this corresponds to moderate lymphocytosis. Thus far neither ependymitis nor meningitis has been found at autopsy. Achard described a series of degrees of somnolence varying from terminal coma to intermittent somnolence. Another peculiar mental state is one of astonishment or wonder. The head is not rested on the pillow but held fixed, the gestures are catatonic, and winking occurs only at long intervals; the subjects fear to move, do not comprehend, and the face is an inexpressive mask. This simulation of astonishment is akin to sleep and the subject may come out of it suddenly. The condition suggests the astonishment of a subject just roused from slumber, but is persistent. Motor disturbances comprise flaccid paralysis, spastic states, myoclonus, etc. Netter originally believed that these patients did not have a lymphocytosis, but has since learned that this phenomenon is present at the outset and wears off, while in tuberculosis of the meninges it increases with the progress of the disease.

Myoclonic, myotonic, and neuralgic forms of lethargic encephalitis have been isolated and in the *Bulletin Médical* for March 6, 1920, xxxiv, 13, Sicard, Salmont, and others graphically describe the last named.

The algic form may occur alone or with the myoclonic form. The suffering is acute and Sicard believes that severe neuralgia in some one nerve distribution may sometimes be the sole symptom of the disease. On the other hand the entire neuraxis may seem to participate in motor or sensory manifestations. Salmont in a case with neuralgia of one arm made a diagnosis of radiculitis cervicobrachialis. It served as a prodrome of a typical case of the fully developed disease. Léri speaks of intense facial or radicular neuralgia as an abortive expression of the disease. Netter saw terrific neuralgic pains subside under mild measures or spontaneously. On the other hand, Claude describes the myotonic form as he saw it, one patient resembling greatly a subject of paralysis agitans. This was manifest in the facial expression, gait, and tremor. Along with this syndrome was the ocular disturbance of encephalitis lethargica. The tremor of the myotonic syndrome was seen in one case in association with myoclonus. Catatonia has also been seen. Death with persistent hiccough may have stood in some relationship with diaphragmatic myoclonus. As an example of the rich symptomatology of the disease, a case of Galliard's may be cited in which the presence of a severe stitch in the side led to a diagnosis of pleurisy, but this apparently was only a forerunner of encephalitis—one of the neuralgiform prodromes which tend to involve the intercostal nerves.

In the *Bulletin Médical* for March 6, 1920, xxxiv, 13, Guillain gives the results of a study of six cases of this malady with reference to the behavior of the reflexes. In four subjects he found abolition of reflexes of the lower extremities—patellar, tendo Achillis, medioplantar, posterior tibiofemoral, posterior peroneofemoral—while in the upper extremity there was abolition of the styloradial, radiopronator and cubitopronator and olecranian reflexes and those of the flexors and biceps. The cutaneous and so-called defensor reflexes and those of medullary automatism were normal throughout. This abolition of reflexes seen in certain cases only with preservation of other reflexes may have a prognostic significance, for of the four cases which presented this dissociation all ended fatally, while the two which did not present this abolition recovered.

"FULL-TIME MEN" AND GENERAL PRACTITIONERS.

MEDICAL education has reached a point where the status of practitioners in the medical schools should be defined. "Full-time men" are getting to be all the rage. In the few schools which can afford it, even younger instructors and associates are to an increasing extent men who have no private practice, who divide their time between laboratory, wards, dispensary, and classes. Obviously, with this assortment of activities, the full-time man's time is full indeed. He is working in a place where no test is too difficult to perform, no procedure too complicated to carry out. Instead of dealing with the heartaches and the thousand natural shocks of family life, he deals with patients who are under orders, with doctors and nurses who have been trained and who have no other cares. He need not feel obliged to give medicine just for the sake of "doing something." In short, he is a relatively free agent who can spend all his time being scientific.

Now, so far as the students are concerned, this reacts most beneficially. Students should see medicine at its best. They should be taught by men who have time to be investigators, who do not have

to fight and harangue in order to get their directions carried out. From an educational point of view this arrangement is far better than that of taking the man with the largest practice and reputation, making him a teacher, having him rush from his practice to his classes, never giving sufficient time to his teaching, always giving the same lectures from year to year.

Are we, then, to do what we can to speed the extinction of the practitioner-teacher and bestow our favors upon the full-time man? This would clearly be bad policy unless we intend to make medicine altogether an institutional affair and eliminate private practice, an idea so impracticable that it deserves no sponsors. In the first place, the men who are selected for full-time teaching and research are, professionally speaking, practically all born in laboratories. Chemistry, bacteriology, and pathology figure so largely in medical teaching to-day, that a man without some achievements *in vitro* had better not regard himself as suitable material for a full-time teacher. This being the case, the schools are running the risk of turning out men even worse equipped for private practice than they are now. Graduates will be likely to continue regarding diagnosis and pathology as be-all and end-all, and those measures practicable for the relief of those patients who are sick at home, with a busy, worried wife or mother for a nurse, will be foreign to them. However much the full-time man with a laboratory past may realize the limitations and demands of medicine practised in private homes, this man cannot give the student the point of view which one well-trained in private practice can give.

To supply this point of view we have our choice of requiring that full-time teachers shall have engaged in private practice for a period of years before entering upon their professional work, or of continuing to rely upon professors of clinical medicine or surgery, etc. Probably the latter alternative is to be preferred if the men chosen have not the kind of practice where quality of work is sacrificed to quantity, in the interests of the exchequer. Far better use for purposes of clinical teaching the man who is "too good a doctor to make money"—in other words, the man who gives each patient such careful attention that he cannot have huge numbers of names in his appointment book. Diagnostic speed kings may do well enough financially, but they are not qualified to head students toward good medical work. Full-time men are indispensable to the best medical teaching. They should guide the teaching policies of their respective departments. But the instruction they give must be supplemented by the personal teaching of conscientious practitioners, who do more than anyone else to bring modern medicine into the homes.

THE PHYSICIANS' HOME.

THE family physician, like the family horse, having carried the family burdens, the one on his mind and in his heart, the other on his back or by his muscle, through the best years of his life, is not always made the object of solicitude and care when the days of burden-bearing are nearing an end. This was true in the "good old days," when the "village doctor," and the country "saddle-bags" played so important a part in the life of the community; it is none the less true in these days of organized medical care and public health service, of "scientific philanthropy" and welfare societies.

It has long been the accepted belief that physicians, as a class, are not specially adept at money making and money saving. Even the high-priced specialists of the larger cities, with few exceptions, have given the public little cause, by virtue of their large holdings or keen investments, to change this estimate of the business acumen of the medical profession. And yet, strange as it may seem, little thought has been given the how and where of the doctor's livelihood in the latter years of his life, when he can no longer respond to the urgent and strenuous demands of the sick room or operating amphitheater. It is possible, therefore, to look about and to see or to learn of many a physician who is eking out a threadbare existence after having served his part of the community long and well.

Now, however, there is promise of better things for physicians who, through age or infirmity, are no longer capable of taking their accustomed place in the welfare of the community. Dr. Wolff Freudenthal of New York City has conceived the idea of a home for just such doctors. A committee has been formed to raise funds, a charter has been granted by the New York Legislature, and the nation-wide movement is fairly under way. Dr. Robert T. Morris, of 616 Madison Avenue, is president of the corporation, and Dr. Albert G. Weed, of 152 West 57th Street, is treasurer. It is to be hoped that doctors who are still active and the public at large will respond to this worthy appeal. The plans as outlined make provision for the wives of physicians. No mention is made of women physicians, but it is assmued that they are included in this praiseworthy undertaking.

THE MURDER OF PHYSICIANS.

CASES are by no means rare in which members of the profession meet their death through the act of an irresponsible patient, the most conspicuous example of late years being the murder of the distinguished Pozzi. Owing to the eminence of the victim the case was the occasion of widespread comment, but since that date several other medical men have met a similar fate. Hardly a medical man of any prominence but has had his life threatened by a patient with a fancied grievance or by some male member of a family in which a death, or some untoward result short of death, has occurred. We recall one sudden death in a mysterious manner of a comparatively humble practitioner which was not fully explained and was thought to have been a possible suicide by poison. A medical friend filled out the death certificate and there was no inquest. It was known privately that the deceased had been

threatened with death by the husband of a woman who had claimed some malpractice. Practitioners have been known to pack up over night and move to distant parts under circumstances which leave room for the belief that they had been threatened with death. We do not of course in this connection include cases in which the practitioner has been in some way culpable by violating the laws or usages of society.

In *El Siglo Médico* for February 16, 1920, lxvii, 3451, is an account of the murder of a well known practitioner of Bilboa, Dr. Villasante, member of a distinguished family and known for his humanity in treating the poor without fee, who was shot dead by the husband of a woman who at the moment lay dead in her bed. The murderer had never shown any homicidal tendency. The revolver had not been in his possession until shortly before the act, and the suggestion was of deliberate homicide. Aside from the eminence of the victim and the fact that the dead woman was a free patient no comment is made.

Preretinal Hemorrhage.

Hemorrhages occurring in front of the retina are far from infrequent and are rather easy to differentiate with the ophthalmoscope. They are important to know about because of their relatively benign prognosis, and their peculiar etiology and treatment, which latter is more especially of a general nature. The prognosis, which at first might seem to be rather bad, since vision is almost totally or even completely lost, is in reality much less serious than that of intraretinal hemorrhage. The important structure of the retina is not directly involved in the process, and if the blood pressure and renal permeability be carefully watched absorption of the blood collection, with an almost complete return of the visual acuity, may be obtained within the space of four or five months. As to the etiological factors of preretinal hemorrhage generalized arteriosclerosis, or an arteriosclerosis confined to the retinal system is invoked, likewise arterial syphilis and affections of the heart and kidneys. Considerable importance is to be attributed to high blood-pressure. Preretinal hemorrhage, the consequence of leucemia or hemophilia, is more difficult to avoid or to be influenced by treatment. Local blood-letting over the temple is of little avail, but miotics, such as eserine or pilocarpine, are really valuable if the ocular tension is increased. The treatment, however, is above all else a general one. In order to reduce an excessive blood-pressure there is nothing equal to fasting during the first few days, after which a milk diet is taken, with the obvious intention of relieving the autointoxication of the patient. The volume of liquid ingested should likewise be reduced and in addition a drastic purge should be given once or twice during the first week of treatment. After this a more ample diet may be allowed, but it should be lactovegetarian as much as possible and salt must be proscribed. Diuresis is to be maintained with niter, uva ursi, or theobromine. The organic iodides are the only medicaments that may occasionally have their indications. Calcium chloride and the hepatic extracts are of use in hemophilia, while the genital opotherapeutic extracts, associated with tepid hydrotherapy, will be found useful in women approaching the menopause or those suffering from difficult menstruation. Absolute mental and physical rest must be enjoined, and a nutritious diet in otherwise normal subjects will help not a little in bringing about complete absorption of the blood.

Cacodylate of Soda in Paralysis Agitans.

Recently Sicard, Lhermitte, and Quesnel have reported happy results in muscular contractures from the use of arsenicals which announcement moved Maréchal to test the use of the cacodylates in paralysis agitans (*Gazette des Hôpitaux*, January 24, 1920, xciii, 9). The patient at the age of 44, as a result of certain disappointments, developed a tremor of the hands and rigidity of the arms and legs. Five years later she had become completely incapacitated and was interned in a hospital. At this time she suffered from tremor of the hands, feet, and lips, with pronounced muscular rigidity, the head being immobilized and the face fixed. The arms were as if fused to the body, from which they could hardly be separated. The lower extremities were much contractured, walking was impossible, as was also standing. The viscera were in good condition. The cacodylate was now begun in dosage usual for syphilis, increasing in 16 days from 1.5 to 6.5 gm., the patient consuming in all 32 grams. The remedy was given each time intravenously. It was quite well borne save that the second injection of the series caused considerable shock. When 4 gm. had been reached no benefit was apparent, but when the dose reached 5, a distinct change for the better appeared. Muscular rigidity became less marked and the subject began to regain the use of her functions in some degree and could get about some with a cane. Apparently the tremor was not correspondingly benefited. The author admits that he might have awaited the further outcome of the case, but having obtained an amelioration, even if transient, of the disability he believes himself justified in publishing it as soon as possible.

Did Sydenham Describe Lethargic Encephalitis?

It has been stated that an Englishman can be found to receive credit for priority in most discoveries, but it does not often happen that a man of some other country is the one to make the announcement. In the *Journal de médecine de Bordeaux* for February 25, 1920, xci, 4, Mauriac publishes a translation of portions of Sydenham's writings on the continued fevers of 1673-5. The fever referred to resembled fever in general in many ways, beginning with severe headache and backache, and often ran its course in two or three weeks. The most noticeable symptom was a species of coma and in some cases this state persisted for several weeks. Those who suffered from coma awakened from the eighteenth to the thirtieth day, but before that period roused themselves only to drink, after which they fell back asleep. Some, of course, never came out of the coma. Those who did not develop coma showed some delirium, but were never violent. In the somewhat extended description Sydenham frequently used the term soporific to indicate the mental state and oc-

casionally the word lethargic, but at the close proposes the term "comatose fever" for the new type of malady, for such it doubtless was. Like most early descriptions this leaves much to be desired. So acute an observer would hardly have neglected to mention the ocular symptoms had any been present. We do not obtain much idea of the incidence of the disease nor of the mortality.

News of the Week.

Drive for Mental Defectives. — The Home and Farm Institution for Mental Convalescents, Inc., with headquarters at 198 Broadway, New York City, has begun a drive for $250,000 with which to establish an institution for the treatment of mental defectives. Twenty-five non-sectarian organizations, under the leadership of Joseph B. Olidort, are taking part in the campaign. A site in Sullivan County has been donated by Mr. Olidort, who for years has been director and vice-president of the People's Hospital. The officers of the organization are as follows: Justice Aaron J. Levy, chairman of the board; Dr. J. Glass, Justice Sampson Friedlander, the Rev. Dr. Blum, Justice Jacob S. Strahl, Nathan Ferber, Samuel A. Levene and Dr. Herman P. Posner; Harry Schiff, treasurer; Harry Wolkoff, recording secretary, and Evelyn Bebell, executive secretary.

Alcoholism Decreasing.—Frederick D. Greene, General Secretary of the United Hospital Fund, New York City, has announced that a survey of several hospitals shows a drop of from 70 to 90 per cent. in alcoholic cases, compared with last year. The City Board of Ambulance Service reports a large decrease in all cases, including intoxication. In January and February, 1919, the Board reported 412 and 364 alcoholic calls, respectively; this year the calls for the same months were 307 and 133, respectively. Bellevue Hospital figures showed 228 calls for intoxication during January and February, 1919, and a total of 31 for January and February of this year. Mr. Greene reports that 7,000 new patients a year can be accommodated at Bellevue in consequence of the reduction in the number of alcoholic patients.

Summer Camps for War Victims.—The ex-service men of the Seward Park Rehabilitation Center, New York City, have started an informal drive to obtain funds with which to furnish their summer camps at Bear Mountain and Fire Island. The men, who were wounded or gassed overseas, are taking vocational training, under the provisions of the Federal Board for Vocational Education, in the Educational Alliance Building on East Broadway.

Milk for American Babies.—The Milk for Children in America Fund, New York City, is making an appeal for funds for supplying milk to needy and sick children of the city.

Food Drafts for Austrians Approved. — Chancellor Karl Renner has cabled the unqualified approval of the Austrian Government of the plan of forwarding food drafts to the destitute people of that country. In his cable to the American Relief Administration European Children's Relief Fund, 115 Broadway, New York City, of which Herbert Hoover is Chairman, Chancellor Renner says: "During the first weeks after the establishment of the American Relief Administration European Children's Fund more than 50,000 Austrian citizens received food through the agency of this organization. On the presentation of the drafts at the Vienna warehouse their lucky and happy holders received American food without trouble or delay."

Texas State Board of Medical Examiners Reorganized.—At its annual meeting recently held in Dallas, the Texas State Board of Medical Examiners was reorganized with the election of the following officers: *President,* Dr. D. S. Harris of Dallas; *Vice-President,* Dr. Robert Y. Lacey of Pittsburgh; *Secretary,* Dr. T. J. Crowe of Dallas.

Drug Ring Discovered.—The discovery of the headquarters of a great drug ring in New York City followed the arrest of two alleged traffickers recently and the confiscation of cocaine and heroine estimated at more than $100,000.

Health Centers Bill Approved.—The New York State Charities Aid Association has passed resolutions endorsing the Sage-Machold bill, now pending in the Legislature, which provides for a comprehensive extension of the public health work of the State through the establishment of a system of Statewide health centers, with an appropriation of State funds to supplement the expenditures made by the communities in carrying on the work. The bill aims to take modern medical, laboratory, hospital, and dispensary facilities to the doors of the people of moderate means and those who live in rural and industrial communities.

Post-Graduate Endowment Fund.—Mrs. Henry R. Rea of Pittsburgh, Pa., has contributed $100,000 to the New York Post-Graduate Medical School and Hospital two million dollar endowment fund. The gift was made in memory of the parents of Mrs. Rea, Mr. and Mrs. Henry W. Oliver of Pittsburgh.

Bronx Physicians Raise Fees.—Members of the Bronx Medical Alliance have decided to raise fees for outside calls from the old charge of $2 to $3: For office visits, from $1 to $2; for confinement cases, from $30 to $50, and in anesthesia cases from $7 to $10. Prices may vary, however, according to neighborhoods.

Municipal Civil Service Positions Open.—The Municipal Civil Service Commission of New York City has announced examinations for positions as radiologist at Bellevue Hospital at a salary of $3,500 a year, and as pathologist, New York City Children's Hospital and Schools, Randall's Island, at $2,100 a year.

Merritt H. Cash Prize.—The Merritt H. Cash prize of the New York State Medical Society has been awarded to Dr. Herman B. Sheffield of New York City for his essay on infantile paralysis.

Memorial to Woman Physician.—Friends of Dr. Sarah Bond Fraser of Boston, who died in June of last year, plan to erect a memorial in her honor. The treasurer of the committee is Mrs. A. W. Goodnow of 27 Burroughs Street, Jamaica Plain, Mass.

Dr. Seth M. Milliken of New York City, who was recently sued by a patient for $200,000 for alleged false imprisonment in the psychopathic ward of

Bellevue Hospital, was exonerated by the Supreme Court jury.

War Nurse Made Superintendent of Massachusetts Hospital.—Miss Vera A. Allen of Toronto, Canada, who was cited by Field Marshal Haig for her efficient work at the base hospital at Damnes-Camières, France, has been appointed superintendent of the Lynn Hospital to succeed Dr. Hilda A. Simon.

Dr. M. Douglas Flattery has been appointed a member of the Harvard Cancer Commission.

Dr. Horatio Robertson Storer, a retired physician of Newport, R. I., is said to be the oldest living graduate of Harvard, this distinction having come to him through the recent death of Charles French of Newtonville, Mass. Dr. Storer, who was born in 1830, was graduated in the class of 1850.

Dr. G. Camby Robinson, dean of the medical department of Washington University, St. Louis, Mo., has accepted the appointment of dean of the School of Medicine of Vanderbilt University, Nashville, Tenn. He will enter upon his new duties July 1, taking up the work of organizing and building up the medical department under the new four million dollar endowment recently made by the General Education Board of the Rockefeller Foundation.

Dr. C. A. Edwards of Dayton, Ohio, has been missing since March 15, when he left home to go to Cincinnati for the purpose of undergoing an operation.

Charitable Bequests.—By the will of the late Mrs. Lois B. Cassatt of Philadelphia the sum of $50,000 is bequeathed to the Bryn Mawr Hospital.

By the will of the late Mary Ann Elliott of Philadelphia bequests are made as follows: Home for Incurables, $10,000; Methodist Hospital, $5,000; Frankford Hospital, $500.

By the will of the late Herman Prager of Philadelphia bequests are made as follows: Jewish Hospital, $10,000; Mt. Sinai Hospital, $5,000; Jewish Sanatorium for Consumptives at Eagleville, $1,000.

By the will of the late Gustav A. Schwarz of Bala the sum of $5,000 is bequeathed to the Lankenau Hospital of Philadelphia.

By the will of the late Mary E. Rowland, formerly of Philadelphia, who died at Atlantic City, bequests of $1,000 each are made to the Home of Our Merciful Savior for Crippled Children's Seashore House at Chelsea, Atlantic City, and Rush Hospital for Consumptives.

By the will of the late Florence W. Holbrook of Philadelphia the sum of $500 is bequeathed to the Episcopal Hospital.

By the will of Frank A. Sayles, who died in New York on March 9, the Memorial Hospital in Pawtucket, R. I., will receive $100,000.

By the will of the late Dr. Hosea B. Burnham of Manchester, N. H., among other bequests a gift of $40,000 was left to Dartmouth College, $35,000 to the New Hampshire State Hospital, $14,000 to the Exeter College Hospital.

Obituary Notes.—Dr. William James Morton of New York City, died recently of cardiac disease, at Miami, Fla., at the age of seventy-six. Dr. Morton, who was the son of Dr. William T. G. Morton, the first surgeon to demonstrate to the medical profession the use of ether for purposes of narcosis in surgery, was graduated from the Medical School of Harvard University in 1872. He was a member of the Medical Societies of New York County and State, the American Medical Association, the American Electrotherapeutic Association, the American Roentgen Ray Society, and the New York Academy of Medicine.

Dr. George W. Thompson of New York City died April 3, at the age of sixty-five. He was graduated from the Eclectic Medical College of the City of New York in 1885.

Dr. Willard Young Croxall of Aberdeen, Wash., died at Portland, Ore., March 12, at the age of fifty-one. He was graduated from Jefferson Medical College, Philadelphia, in 1897, specializing in ophthalmology and otorhinolaryngology. He was a member of the American Medical Association and of the Pacific Coast Oto-Ophthalmological Society.

Dr. Helen E. Hill of Brooklyn, N. Y., died March 20, in her eighty-first year. She was graduated from the Eclectic Medical College of the City of New York in 1881. She retired from active practice in 1913.

Dr. Edward C. Register of Charlotte, N. C., for twenty-eight years editor of the Charlotte *Medical Journal*, died February 18, at the age of sixty. He was graduated from New York University Medical College in 1885, and had long occupied a prominent place in the medical affairs of his State.

Dr. Martin T. Balsley of Joplin, Mo., died recently after a long illness. He was graduated from the Medical College of Indiana, at Indianapolis, in 1881, where he practised for a few years.

Dr. Pierre S. Starr of Hartford, Conn., one of the oldest physicians in the city, and a veteran of the Civil War, died March 11 at the age of eighty. He was graduated from New York University Medical College in 1862.

Dr. Ernest M. Jordan of Boston, Mass., died March 14, at the age of forty-eight. He was graduated from the Boston University School of Medicine, in which institution he was for seven years professor of neurology. Dr. Jordan was a member of the American Medical Association, the Massachusetts Homeopathic Society, the Boston Surgical Society, and other organizations.

Dr. Phoebe Anna T. Williamson, a retired physician of New York City, died at the Hahnemann Hospital, March 21, at the age of seventy. She was one of the founders of the Women's Hospital in Poughkeepsie, and for twenty years was attached to the Eastern District Hospital of Brooklyn.

Dr. Jerome Gill Ackinson, retired, of Brooklyn, N. Y., died of influenza March 22.

Dr. Warren L. Ayer of Owego, N. Y., died March 26, at the age of seventy-seven. He was graduated from Long Island College Hospital in 1868.

Dr. Vincent J. Campisi of Brooklyn, N. Y., met his death at the hands of an assassin March 25. He was born in Italy in 1887, came to this country at the age of twelve, and was graduated from Long Island College Hospital in 1914.

Dr. Francis E. Bingham of New York City died March 25 at the age of thirty-one. He was graduated from New York University and Bellevue Hospital Medical College in 1913.

Dr. Helene S. Lassen of Brooklyn, N. Y., died March 25. She was graduated from the New York Medical College and Hospital for Women in 1871, and had practised in Brooklyn for forty years. She was one of the organizers of the Memorial Dispensary for Women and Children. She was a member of the Kings County Homeopathic Medical Society.

Dr. Edwin M. Goodwin of Toledo, Ohio, died suddenly March 17, at the age of seventy-eight. He was graduated from Albany (N. Y.) Medical College in 1863.

Dr. Stephen J. Johnson of Lowell, Mass., died March 22, at the age of fifty-five. He was graduated from New York University Medical College in 1877.

Dr. Jacob R. Shellenberger died of heart disease at Philadelphia on March 20 at the age of seventy-nine years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1867. He was President of the Physicians' Aid Association affiliated with the Philadelphia County Medical Society. He was a member of the Philadelphia County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Obituary.

JOHN A. LEE, M.D., F.A.C.S.

BROOKLYN, NEW YORK.

Dr. John A. Lee, President of the Medical Society of the County of Kings, died at his home in Brooklyn on Sunday of this week of cancer of the lungs. He was born in New Britain, Conn., in 1872, and was graduated from the Yale Medical School in 1897. He served as interne in St. Mary's Hospital, Brooklyn, and on leaving there began practice in that borough. Since 1908 he had been attending surgeon to St. Mary's Hospital. During the war he served as surgeon-in-chief on the hospital ship *Comfort,* and at the close of hostilities received his discharge with the rank of Commander. He was one of the pioneer workers with the *x*-rays in this country and suffered extensive burns which resulted in cancer, for which he underwent several operations, and finally died from metastasis in the lungs.

In Memory of Dr. Elisha Kent Kane.

On March 30, 1920, under the direction of the Master of the Lodge, Dr. Terry M. Townsend of New York City, the Kane Lodge, No. 454, F. & A. M., celebrated the one hundredth anniversary of the birth of Elisha Kent Kane, the famous Arctic explorer, for whom the lodge is named. The celebration, which was held in the Grand Lodge Room of the Masonic Temple, New York City, was to have been made the occasion of the award of a Kane Lodge gold medal for distinguished achievement in exploration to Rear-Admiral Robert Edwin Peary, for his success in reaching the North Pole. Admiral Peary was a member of the lodge, to which he had given many souvenirs of his several Arctic expeditions. His death did not interfere with the award; the medal was presented to Mrs. Peary and was received by their son, Robert E. Peary, Jr. Bishop Charles Sumner Burch, Rear-Admiral James H. Glennon, Job E. Hedges and Robert H. Robinson, Deputy Grand Master of the Order, were among the speakers. Miss Julia Arthur recited the "Battle Hymn of the Republic," and various musical numbers were rendered. The salutation was by Dr. Terry M. Townsend.

Dr. James Parton Haney of New York City, Past Master of the Lodge, gave the following account of the life of Dr. Kane:

Few of the present day realize the warmth of patriotic pride which caused the founders of this Lodge to call it by the name of Kane. But in 1857, when the Lodge was established, this name was a household word, and the country rang with applause for the intrepid discoverer. Twice he had ventured into the Arctic night in search of the expedition of Sir John Franklin. For two years his little company had suffered the tortures of hunger and disease. He had probed the mysteries of the frozen North and had seen open before him an unknown sea. He had planted the standard of the United States nearer the pole than any flag had flown before. Yet with all this he was not a sailor—not a professional explorer—only a surgeon in the United States navy, who had not reached his thirty-third birthday when he assumed command of the expedition which was to make his name famous the world over.

Elisha Kent Kane was a modern Odysseus whose whole life is a tale of high adventure. When this tale is told it reads more like a song of Homer's or a page from Malory, than the recital of what a slim and sickly man had done in a dozen crowded years. The more one reads of Kane's life, the more the wonder grows that one so scantily endowed with physical strength could by sheer will power have been able to accomplish so much. It may truly be said that he was never a well man, yet with a serious lesion of the heart he lived through half a dozen attacks of contagious fevers and labors like the fabled tasks of Heracles.

Kane was born in Philadelphia on February 3, 1820. He died in Havana, Cuba, just after his 37th birthday. As a boy he had shown his adventurous spirit, but was so little studious that his father was doubtful of his future. The former planned to send him to Yale, but later decided on the University of Virginia. Here the lad found himself at home and made rapid progress. The languages and mathematics appealed to him, but an even keener interest was elicited by the work he elected to pursue in physical geography, mineralogy and chemistry.

It was at this juncture that his first serious illness overcame him. This was a rheumatic attack which speedily involved his heart. It obliged him to leave the university dangerously ill and, at the age of eighteen, brought his formal studies to an end. "The doctor told me," he said, "that I might live a month or half a year, or that I might be struck down in half an hour."

The presence, however, of this Damoclean blade seemed only to stimulate him. The imminence of death spurred him to action, that in the brief time he felt was his he might greatly achieve. As a compensation for his faulty heart, nature endowed him with a mentality of extraordinary sensitiveness and activity. "His nerves," says one of his friends, "tingled and rioted with irritation." He seemed driven forward by inner forces not always under his control, but in the end he learned to master and direct this energy to his one great aim.

In October, 1840, while not yet twenty-one, he entered the Pennsylvania Hospital—"Blockley," as an interne and medical student. Here he became in a few months senior resident physician. The heavy duties of his office, together with his study of medicine, were not, however, sufficient to absorb his flooding energies and shortly before his graduation we find him writing an elaborate thesis on the newly discovered secretion called "Kyestein." It is worthy of note as an indication of his intellectual acumen that this undergraduate

study, written before its author was twenty-two years of age, drew the general attention of the medical world, and later was widely quoted in the textbooks of the subject.

That he might have a respite after his strenuous hospital experience, his father applied at his graduation for a warrant for his examination as a surgeon in the navy. The young doctor at first demurred, then consented, passed the test handsomely, and shortly afterward sailed for the East, as the physician attached to a special embassy to China. During the slow voyage, with many stops, Kane had revealed to himself his passion for exploration. He traveled in India and made a hurried trip to Ceylon before reaching China. The treaty negotiations were closed in a few months and he at once set off for the Philippines. There he traveled over Luzon from Manila to the Pacific coast, bathed in the forbidden waters of the Asphalt lake and descended to the bottom of the great volcano "Tael"—a feat which only one European had essayed before, and he without success.

As the special embassy's work was done, Kane might now have returned to the United States, but he determined to remain to practise, until he had acquired funds for extended travel through the East. Accordingly he resigned his post as physician to the legation and set up an office on Whamposa Reach of the Canton river. The chaplain of the mission there, describes him as "smooth and florid of face, very youthful looking, of a delicate form, a bright eye and enthusiastic manner—all hope and ardor."

Six months later saw the enthusiast critically ill with "rice fever," the first of the many infectious diseases he was to know. He was nursed back to health but resolved to abandon his practice and return home by the overland route. The trip was begun, and extended itself in various directions. He visited Borneo and Sumatra, and then passed back to India. There he was taken into the suite of Prince Tagore, who afforded him every facility for scientific research. He reached the Mediterranean in April of 1845 and bade goodbye to the patron under whose safe conduct he had traversed Persia and Syria.

Letters from Prince Tagore to Pasha Mehemet Ali of Egypt secured for Kane a special "firman" for his protection, and with this he set about exploring the ruins of the Pyramids and Thebes. "Here," he says, "my life was a very wild one—I wore native dress, with a beard so long I had to tuck it in." And later he makes reference to a hot scrimmage with a party of Bedouins, in which he received a wound in the leg. To cure this he betook himself to a hospital at Alexandria and the plague seized and all but killed him.

As soon as he was well enough to travel he set out for Greece. Her mountains he slowly toured on foot, then journeyed northward through Switzerland and Germany. It is interesting to note that in the former of these countries he so carefully examined the glaciers that his diaries in the Arctic are filled with references to them. He passed through France to England and thus back to America in the winter of 1845.

He now resolved to settle down to practise in Philadelphia, and went so far as to secure an office, but adventure did not cease to call him and before many months he was with Commander Reed as assistant surgeon in the frigate *United States*, bound for the coast of Africa. Here his nemesis again overtook him, and he was invalided home prostrated with "coast fever." How virulent was this attack may be judged from the fact that only after the sixth week was he sufficiently recovered to permit of his being lowered over the frigate's side to a homeward-bound transport. The effects of this illness he carried ever afterwards.

He reached Philadephia in April of 1847, a very sick man, but with courage still undaunted. The Mexican war was in progress and he was determined to see service. His influence procured him an appointment as inspector of field hospitals, and by November he was well enough to sail for Vera Cruz, there to engage in fresh activities which landed him once more in the doctor's hands. This time the cause was a lance thrust in the abdomen, received from one of his own escort, when the latter threatened to butcher in cold blood prisoners whom Kane defended. His Egyptian hospital experience promptly repeated itself, and typhus fever followed. This convalescence, as might be expected, was slow, but by January of 1849 he was again at sea, but far from well. The great adventure, however, was drawing nearer.

When he returned in October he found a world moved to its depths by the appeals of Lady Franklin for the rescue of her husband and his companions. They had gone in search of the northwest passage and had not been heard of since 1845. The response of the United States to the appeal was widespread, and the public held the government committed to aid. Kane promptly volunteered as surgeon of the rescue party, which came to be known, from the generosity of its backer, as "the first," or United States "Grinnell Expedition." No response from Washington came to the volunteer for several months, then suddenly while he was on the shores of the Gulf of Mexico he received a curt telegram, instructing him to "proceed forthwith to New York for duty upon the Arctic expedition." In less than eight days he was in New York and a few hours later saw him aboard and at sea. His preparation for the great adventure had begun.

Kane now ranked as past assistant surgeon and senior medical officer of the expedition. Lieutenant De Haven commanded. The start was made in May, 1850, and the return to New York in September, 1851. For nine of the sixteen months the vessels were ice-locked and adrift in the frozen sea. But Sir John Franklin had not been found, though news had come of his winter quarters at Beechey Island in 1845-46. This revived hopes of his survival and it was determined that the field of search should be more thoroughly explored. Dr. Kane was eager to participate. By manifold efforts and largely through the further generosity of Mr. Grinnell of New York and of Mr. Peabody of London, he was given the opportunity to take out the same brig—the *Advance*—in which he had sailed with De Haven. The great adventure had come at last.

The little vessel turned once more to the North on May 30, 1853. She was bound for Smith's Sound, through which the commander hoped to reach an open Polar sea. The hope was never realized. The voyage to the Sound was safely made, but there in Rensselaer Bay the ice caught her and held her, and, to use Kane's words, "the same ice is round her still."

There followed two stern winters with lessening fuel and supplies, and increasing inroads of disease. Death took two of the little party and stared the others in the face. They capitulated at last. The stripped and desolate ship was abandoned and the long and hazardous journey to the South begun. Incredible courage made it, but it was a feeble and famished band which hailed the Danish "oil boat" weeks later under the shadow of Karkamoot. For four and eighty days the commander and his men had fought the ice-pack and the storm, had sailed thirteen hundred miles and had won their goal with but one small boat left of all their equipment. The great adventure was drawing to its close.

A relief expedition under Lieutenant Hartstene, U. S. N., with Dr. John K. Kane, a brother of Elisha, had been meanwhile searching for the lost *Advance*. It found the survivors and brought them back to New York in October, 1855. They had been gone for thirty months. Kane resolutely set about writing his story, but felt his power wane. Small wonder! The marvel is that his frail body should have survived so long. Fever, scurvy, and rheumatism had racked it. Intolerable fatigue had destroyed its recuperative power. The active brain still worked, but the overwrought heart was failing. Says he, as he labored over his final chapters, "Something is the matter; I get weaker every day." This was true. The shrouded Presence which had brooded for months in the fetid cabin of the *Advance* would no longer be denied.

A hurried trip to England was taken in October, 1856, with the hope that it would help, but the fogs of London made the laboring heart worse instead of better, and in a few weeks the patient left England for Cuba. His old enemy—rheumatism—now tortured him and his breathing was much affected. He reached Havana on Christmas day, and for a few weeks seemed better, but early in February he became paralyzed and

a week later the stout heart ceased to beat. Without a sigh, from the slight and wasted body, the valiant spirit passed. The great adventure was quite finished —the greater just begun.

Correspondence.

NO PHYSICIAN OR SURGEON AS YET IN THE HALL OF FAME.

To the Editor of the Medical Record:

Sir:—Soon there will be the fifth quinquennial election to the Hall of Fame. The first took place in 1900 immediately after the funds had been given anonymously for the building of a permanent monument to the men and women who had contributed most to the nation's well-being and culture. According to the constitution drawn up at the time, it was agreed that at the first election fifty national figures in art, science, and history should be chosen and that thereafter five were to be added every five years.

The method of procedure in placing the name of a man or woman on a tablet in the Hall of Fame is such as to allow no question or doubt as to the person's eligibility. The Senate of the New York University, which is made up of the dean and senior professor of each of the university schools, with the presidents or other representatives of each of the great theological schools in or near New York City, chooses the electors. There are a hundred of these. Every State in the Union is represented by at least one man. These hundred men are chosen by virtue of their eminence in some branch of national culture. They fall into seven main divisions: Authors, presidents of universities and colleges, scientists, professors of history, jurists, high public officials or men or women of affairs, and editors. When the names are sent in to the Senate of the University they are considered on the basis of constitutional qualifications. Not the least important of these qualifications is the one requiring that the nominee must have been deceased at least ten years.

It is with delight that we see, I believe for the first time, the name of a physician among the electors, the chosen one being Dr. Charles H. Mayo, of Rochester, Minn. Perhaps this is a good omen and indicates that one of our own profession may at last be among the immortals. It is true that Oliver Wendell Holmes was a physician, but his name has been chosen for the Hall of Fame as belonging to Group I, authors, of which there are now 14; Group II are educators and number 4; Group III, preachers and theologians, 4; Group IV, philanthropists and reformers, 3; Group V, scientists, 5; Group VI, engineers and architects, none; Group VII, physicians and surgeons, none; Group VIII, inventors, 4; Group IX, missionaries and explorers, 1; Group X, soldiers and sailors, 4; Group XI, lawyers and judges, 4; Group XII, rulers and statesmen, 11; Group XIII, businessmen, none; Group XIV, musicians, painters, sculptors, 2; Group XV, eminent men outside of the classes mentioned, none.

William T. G. Morton, the discoverer of ether anesthesia, was once proposed under Group VII, but failed on the election. I do not know whether or not the constitution of the Senate of the New York University permits a renomination. I hope there will be no barrier to renominating the "Inventor and revealer of anesthetic inhalation, before whom in all time surgery was agony," * and of whom Sir William Osler speaks as follows in his "Man's Redemption of Man": "On October 16, 1846, in the amphitheater of the Massachusetts General Hospital, Boston, a new Prometheus gave a gift as rich as that of fire, the greatest single gift ever made to suffering humanity. The prophesy was fulfilled—neither shall there be any more pain; a mystery of the ages had been solved by a daring experiment by man on man in the introduction of anesthesia."

The next two greatest figures in American medicine and surgery are perhaps Ephraim McDowel and J. Marion Sims. McDowel performed the first rational and deliberate ovariotomy, which he did in 1809, and of course without an anesthetic; his patient living for 32 years after the operation. As is well known, J. Marion Sims (1813-1883) gained for himself a national and international reputation by his invention of the speculum as an instrument for the treatment of pelvic diseases in women and by his perfecting the plastic operation in the vagina for the relief of vesical fistulæ.

The nomination must be sent in to the Senate of the New York University, University Heights, New York City, before May first. Besides erecting the tablet in the Hall of Fame, the Senate of the New York University is now considering collecting the works, where it is possible, of all the men and women who have thus been honored by the nation. They hope in this manner to create a valuable "Americana," open for study and inspection.

I am sending this letter to as many of our American medical journals as possible so that each and every American physician who has a just pride in his profession at heart may do his share to see that a recognition to medical and surgical science equal to that of other professions, is given at last. While there may be other great physicians and surgeons in the past generations who have distinguished themselves so as to be worthy to be classed with "America's Greatest," I venture to say none has surpassed the achievements of Morton, McDowel, and Sims. These were real pathfinders in science and added to human happiness and well-being and the glory of the American medical profession.

Let every American physician send one, two, or all three of these names to the above mentioned address of the Senate of the New York University, stating that this is his choice of America's great men for nomination for the Hall of Fame.

S. Adolphus Knopf, M. D.

*From a monument erected to his memory at Mt. Auburn, Boston.

THE UNJUST AND BURDENSOME REGISTRATION LAW.

To the Editor of the Medical Record:

Sir:—Unless the entire medical profession of New York State has no objection to being examined, registered, and card-indexed annually hereafter on a certain "September Morn" for the rest of their lives they had better protest at once against the bill for the Annual Registration of Physicians by the

Board of Regents of this State, which is now before the Legislature for action. This bill has always been opposed by the organized medical profession of this city. Despite this fact, it was indorsed by their representatives in the recent convention of the State Medical Society. Against this action not even a protest can be entertained, according to the definite ruling of the president of one of the local medical societies.

At the recent banquet of the State Society, at which he was a guest, President Finley of the Board of Regents told the physicians that they would have to accept "annual registration or suffer from quacks." These quacks are an unknown number, existing somewhere up the State. They are said to be practising on diplomas illegally obtained. It is said they can be put out of business only by the proposed legislation, because the local district attorneys will not act against them. As they are certainly less than 100 in number and will in the course of events cease to practise medicine at all, why should the 14,900 physicians who were given the right to practise during good behavior for the rest of their lives be compelled to bear the burden of proving every year that they are still entitled to this privilege?

Any physician failing to appear for registration on account of sickness, disability, or absence from the country on this "September Morn" will have to explain his delinquency to the authorities before he is again allowed to practise his profession without violating the Criminal Law.

JOHN P. DAVIN, M.D.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, March 25, 1920.

Health Insurance.—As I mentioned in my last letter, the medical profession submitted to arbitration, with respect to the capitation fee that those medical men serving under the Insurance Act should receive, and, although the figure 11s. a year for each insured person set by the arbitrators is not satisfactory, it must be taken with the best grace possible. In any event, the settlement is only temporary and can be revised at any time. In the meanwhile, the position of the medical profession should be strengthened by unification and by the establishment of a defense fund. Politically the profession is almost impotent, and will continue to be so until steps have been taken to render it able to defend itself against encroachments on its rights and until it is in position to raise a powerful voice in the settlement of policies in which its interests are directly involved.

It may be of interest and even instructive to readers of the MEDICAL RECORD to see a summary of a report which has just been published by Sir Alfred Watson, British Government actuary, on the financial proposals of the amended National Health Insurance Bill. The benefits and contributions proposed in the measure compare with those now payable as follows:

Benefits	At Present.	As Proposed.	Increase
Sickness per week			
Men	10s.	15s.	5s.
Women	7s. 6d.	12s.	4s. 6d.
Disablement per week.	5s.	7s. 6d.	2s. 6d.
Maternity	30s.	40s.	10s.

Weekly Contributions.	At Present.	As Proposed	Increase.
Employer	three pence	five pence	two pence
Insured men	four pence	four pence	one penny
Insured women	three pence	four pence	one penny

The annual charge on the Insurance Fund toward the cost of medical benefit in respect of both men and women is increased from six shillings and sixpence to nine shillings and sixpence, but on the other hand, the withdrawal of sanatorium benefit from the act is equivalent to the reduction of liabilities by ninepence per annum for each insured person. It is also proposed to increase the yearly allowances to insurance committees from threepence to fourpence per insured person, while the normal allowance to approved societies for administrative expenses is to be raised from three shillings and fivepence to four shillings and fivepence a year. These increases are provided for by the additional contributions. Under the bill a State contribution is provided of two-ninths of the cost of benefits, including the expenses of administration of approved societies and insurance committees, and seven-ninths of the expenditure therefore has to be provided from the contributions of insured persons and their employers. It is estimated that the full value of the benefits of an entrant of 16 years of age, apart from such provision as may be made by the Central Fund in cases of exceptional deficiency on valuation, is the equivalent in the case of a man of ten shillings and sixpence a week, as against a contribution of tenpence, and in the case of a woman of ten shillings and a penny, as against a contribution of ninepence.

According to the best calculation that can be made, the number of insured persons on July 5 next will be 15,850,000, comprising 10,850,000 men and 5,000,000 women. Of the men 300,000 and of the women 150,000 are deposit contributors. The estimated amount of contributions payable under the present acts in respect of this number of insured persons is £20,525,000 per annum and the addition of threepence per week in the joint contribution of employer and employee proposed by the bill increases this sum to £29,750,000. The apportionment of these sums between employers and insured persons is as follows:

	Employers.	Insured Persons.
At present	£9,225,000	£11,300,000
As proposed	15,350,000	14,400,000
Increase	£6,125,000	£3,100,000

On the basis of past experience, and subject to certain other conditions, it is estimated that the expenditure on benefits in the year beginning July 5, 1920, will amount under the present acts, to £20,357,000 and under the provisions of the bill to £28,653,000. The distribution of these amounts, which are exclusive of additional Exchequer grants in aid of medical benefit and analogous services, is given as under:

	At Present.	As Proposed.	Increase.
Men	£14,278,000	£20,080,000	£5,802,000
Women	5,813,000	8,227,000	2,414,000
Deposit contributors.	266,000	346,000	80,000
Totals	£20,357,000	£25,653,000	£5,296,000

Under existing conditions the annual charge on the National Exchequer is £5,770,000. Under the bill it will amount to £6,942,000. The increase under the bill will be £1,772,000. These figures are exclusive of the further sums in respect of medical

benefit which have been voted as grants in aid under the authority of Section 1 of the Act of 1913. The amount of these grants in 1919 was about £3,100,000, and these will be considerably increased by the raising of the capitation figure to eleven shillings. In connection with the first National Insurance Act, the man who was responsible for its working died on March 13, last. When the fierce controversy over the National Insurance Act began, Mr. Lloyd George called Sir Robert Morant, who has just passed away, to the Chairmanship of the Insurance Committee. He had then indeed a hard road to hoe and the task would have broken a smaller man. The Act was distrusted and therefore detested by most of the people interested in it. Medical men, in particular, were most antagonistic to it, the friendly societies viewed it with disfavor and vested interests showed fight. When Sir Robert Morant took the helm a great change came and the Act was administered. He possessed in rare measure that uncommon gift of being able to appreciate and enter into the other man's point of view and he was able, to some extent, to reconcile the medical profession. At the time that Morant died the other day, at the early age of 57, he was the guiding spirit of the Ministry of Health in the establishment of which he had probably more to do than any one man. The death of Sir Robert Morant has left a gap which it will be very difficult, almost impossible, to fill.

New Scheme to Combat Tuberculosis. — The treatment of tuberculosis is to be undertaken by the British Government in a great comprehensive scheme, and it was on account of this that the Ministry of Health removed the sanatorium from their Insurance Bill. It has been felt that one defect in the treatment under the Sanatorium Acts was that the stay of two or three months in such an institution was too brief by far to effect more than a temporary improvement in health. Also, it has been taken into consideration that hitherto only the workman himself received treatment, whereas frequently his wife and children were affected, and for them there was no provision. Thus the relief expenditure was often wasted. It is intended, therefore, to make tuberculosis provision under the new scheme for the whole industrial community. Insured persons in future will include wives or children who may be affected and the relief given may be administered by the county and borough councils. The Government is setting aside a capital sum of £1,000,000 for the creation of settlements for the treatment of tuberculous persons generally. At present the creation of nine such settlements is contemplated, each consisting of 200 houses, so that married persons can be accompanied by their families. It is intended that as far as is possible the residents of these settlements should be employed in useful occupations. Special treatment of tuberculous ex-soldiers is also receiving special attention, and a feature is to be made of it. Of course it has been a matter of common knowledge for some time that the sanatorium treatment of the consumptive has been a comparative failure. It gave temporary relief, but, as a rule, nothing more, and when the late inmate of a sanatorium took up his work or any work he soon broke down. Recently, village settlements and workshops, industrial and agricultural colonies have been initiated as adjuncts to or associated with sanatoriums. In Great Britain there is a colony of this kind at Dapworth, in which industries, agricultural work, gardening, and so on are carried on. The report of the English Interdepartmental Committee recommends the creation of ten village settlements, conducted in a similar way to the colony at Dapworth, which would provide accommodation for from 2,000 to 3,000 soldiers with their wives and families. The colony scheme is an attractive one and on the small scale on which it has been tested up to the present seems to have proved successful. There are several difficulties, however, in the way. Dr. Stanley Tinker, in the *Lancet*, Feb. 28, points out some of these. He foresees, for example, that many working men will not be easily persuaded to abandon their urban homes and settle themselves and their families in an unknown part of the country, however healthy it may be. He recommends an alternative scheme for demobilized tuberculous soldiers, namely, that workshops should be constructed within easy access of the workers' homes, one workshop for training and another for permanent employment, with the various amenities of the up-to-date factory close at hand. Work would be carried on under medical supervision. Dr. Tinker further suggests that the men should continue to be subsidized as follows: While the men are under training they would be in receipt of training allowances from the Ministry of Pensions, as in the case of other disablements, but when training is complete, they would pass automatically to the permanent section, where they would be in receipt of their assessed pension, according to their disability, but which would remain between 50 per cent. and 100 per cent. of the full pension. Their work would be paid at trade-union rates of wages per hour. The colony scheme is on its trial and, as said before, so far seems to have come up to expectations. The medically controlled workshop scheme, as suggested by Tinker, has much to commend it. It is undoubtedly true that men used to living in or near a city will miss many of the amusements and distractions which mark city life. On the other hand, it is a mistake to pamper consumptives, and after all country life should be better for their disease than that of a town, and it may also be said better for their families. It is to be hoped that some practical plan will be evolved by which the tuberculous individual will be made self-supporting and enabled to live under comfortable, healthy conditions.

A Physician Ambassador. — Our newly appointed ambassador to your country is, as is doubtless known, at least to the majority of the readers of the MEDICAL RECORD, a medical man. At the time of the outbreak of the war he was professor of anatomy at McGill University, Montreal, and about a year ago was made principal of that University. When the war began he at once joined up and served ably at the front in a military capacity. Afterward Sir Auckland Geddes, together with his brother, Sir Eric Geddes, were able lieutenants of Mr. Lloyd George. Sir Auckland Geddes is well fitted for the post of British ambassador to America, as he knows and understands its people well. At a dinner given to him at the Pilgrims' Club in

London the other night, in returning thanks for the toast of his health, he spoke the following memorable words:

"I hope and trust that no word will ever fall from my lips which will make mischief, however slight, between such peoples (British and American), for I have the most profound admiration and affection for both. Rather I pray that it may be my lot, if any distemper should arise between them to return to my original profession of physician and act as healer. That, at all events, is my ambition. It is perhaps not without interest that once before this country sent to Washington as its representative a man who held a medical degree. Like me he studied medicine, both in Edinburgh and London. Like me, though a qualified physician, he served in a combatant capacity in war. Like me he had a somewhat variegated career in the service of the State. I refer to Sir Charles Richard Vaughan, his Britannic Majesty's Envoy Extraordinary and Minister Plenipotentiary at Washington, 1825-35.

"Vaughan was contemporary and intimate friend of such eminent American jurists and statesmen as Story and Clay, and he had to deal with the then burning question of the United States boundary with Canada. I believe that when he left Washington it was felt on both sides that there had departed a great British representative, who had done much to strengthen the foundations of an international friendship which last lasted more than one hundred years. I should indeed be a proud and grateful man if when my turn to resign the office comes the same could with truth be said of me."

Death of a Crimean Veteran Medical Officer.—The death occurred on March 13, last, at Paignton, Devonshire, of Dr. Henry Thomas Sylvester, V. C., late 23rd Royal Welsh Fusileers, aged 89. Dr. Sylvester won the highest award for bravery given in the British army on Sept. 8, 1855, when as an assistant surgeon of the 23rd Royal Welsh Fusileers, at the siege of Sebastopol, he went out under a heavy fire to a spot near the Redan, where an officer was lying mortally wounded in a dangerous and exposed situation and dressed his wounds. Dr. Sylvester's bravery was specially mentioned in dispatches by General Sir James Simpson. He afterward took part in the suppression of the Indian Mutiny, including the relief of Lucknow. He retired from the service in 1861 and for many years practised in Westminster.

LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, March 10, 1920.

IN this letter I desire to direct attention to several topics which have been studied recently at the Lyons School of Medicine.

Phosphoric Acid.—Dr. P. Pouget has worked out some problems of the therapeutic use and action of phosphoric acid which are interesting. He finds that at the dose of from five to six grams—but not more—this acid is neither toxic nor steatosing. However, at the beginning of its exhibition the gastric and nervous susceptibility of the patient must be first ascertained and the drug must always be given well diluted. A 1:15 or 1:30 solution is given during meals. The officinal preparation in France contains 1 gram of the acid to 15 drops of the solution, and Pouget restricted his doses to from 20 to 30 drops after meals; the teeth should be carefully cleansed with an alkaline solution to remove all trace of the acid.

Phosphoric acid acts by both of its properties, the acid and the phosphorus. By its acid property it is a stimulant of the gastrointestinal secretions, an antiferment, and regulator of the digestive functions, and by virtue of these qualities it assures a better assimilation and thus relieves the work of the intestine and liver.

As a phosphorizing agent it is especially indicated in digestive and hepatic insufficiency, in depressive states, and psychasthenias. As a eupeptic, a general stimulant and one of the nervous system, and an indirect defender of the liver its use is indicated in tuberculosis. Pouget noted its happy effects in malaria among the troops of the Orient during the war. It is hardly necessary to say that in the latter case the acid has no specific action and is used merely as an adjuvant to the quinine treatment. But it does seem to act favorably in eliminating the toxins and controlling fermentation, thus relieving hepatic and digestive insufficiency so common in malaria. Its stimulating action is a contraindication to its use in all infections in their acute phase, but during convalescence it is highly useful. Finally, phosphoric acid, as is well known, is by far the most easily assimilable of all the preparations of the phosphorus series.

Jugulocarotid Aneurysm.—By the most recent statistics, Dr. M. Leschelier has shown that the surgical cure of jugulocarotid aneurysms should be undertaken with as little delay as possible, because when left alone these aneurysms bring about serious disturbances, such as dilatation of the veins, cardiac disturbances the consequence of an increased blood-pressure in the venous system, respiratory disturbances resulting from compression of the pneumogastric by the aneurysmal sac, and changes in the cerebral circulation.

These aneurysms have no tendency to spontaneous retrogression. Quite on the contrary, infectious complications, increasing ectasis with rupture and fatal hemorrhage are to be feared when surgical treatment is not resorted to. When ligature is done at a late date in the process—that is to say, after the end of three weeks—accidents of septic emboli and ascending thrombosis are prone to occur. Finally, in a few cases it has been found that early ligature may avoid the necessity of ligating the primary carotid, and when the opening is small and its edges are in good condition, suture of the artery may be attempted.

Enchondroma of the Lung.—Primary pulmonary enchondromata have been studied by Dr. E. Reboul, who has had an interesting case in which these neoplasms, on account of their indefinite development and local malignancy differed from benign productions due to rheumatism or rickets developing at the expense of pre-existing cartilage and known by the name of enchondroses. Although growths of this type which have been reported—exception being made of secondary tumors—have been generally small and multiple, in Reboul's case the tumor was quite large, weighing 780 grams. On clinical and radiological

examination it gave the impression of an hydatid cyst, but at operation when puncture was essayed a solid mass was encountered which at first was supposed to be cancer. The growth was enucleated with difficulty, it being included in a pocket formed by the diaphragm, pleura, and lower border of the lung. Microscopically, an osteocartilaginous tumor was found with bone marrow of the fatty type, but distinctly characteristic, interposed between bony and cartilaginous structures. By its histological character this growth reveals the unity of the osteocartilaginous tissues, as well as the histogenetic intimacy of both the cartilaginous and bony portions in the development of tumors of the bones and the cartilage.

2 Anesthesia in Obstetrics.—Paul Appleton believes that, properly used and with perfectly working apparatus, nitrous oxide analgesia and anesthesia, with oxygen, and supplemented by ether in selected cases, can be administered in 99 per cent. of all obstetric cases so as to give the patient a practically painless labor. This can be done at much less expense than is commonly supposed, and, from the purely technical point of view, it saves nervous strain and often true shock, and greatly facilitates the general management of the case.

2. Encephalitis Lethargica.—Hyman Climenko, in an analysis of thirty-four cases treated at Mt. Sinai Hospital, and more than twenty cases in private practice, found that both sexes were equally involved. The highest age was sixty, the youngest fourteen. The writer has seen a patient, aged sixty-eight, and a child seven weeks old, both giving typical symptoms of encephalitis lethargica. By far the greater number of patients were adults. The cases occurred throughout the year, the disease assuming the proportions of an epidemic during the midwinter and early spring months. A careful history always shows that some time prior to the onset the patient was suffering from some acute catarrhal condition of the upper respiratory tract. During the early symptoms, long before the patient gets to the hospital or even thinks of calling a physician, there is usually a stage of euphoria. During this stage insomnia sets in; this may be the first symptom for which the patient consults his physician. At this time there is a rise of temperature and an acceleration of the pulse. The euphoria may soon pass into a real hypomania, with temporary illusions and hallucinations. These illusions are characteristic in that the patient is able to correct them; i.e., when his attention is called to realities he is able to correct the illusion or hallucinations or both. Probably these are not true illusions and hallucinations, but are wrong images received by a diseased brain; a condition that is found sometimes in psychic blindness. There may be a complete disorientation as to time and place, but this too is corrected when the patient's attention is called to the mistake. The memory for past events is good in all cases with the exception of those suffering from severe manias. In the majority of cases the hypomania does not advance beyond this stage; in others a true mania develops. Instead of hypomania an excitable depression may be present. At about this stage choreiform twitching may be observed in many patients. Pain, usually sharp, lancinating, and radiating along the distribution of a peripheral nerve, is one of the early symptoms. Vomiting, drowsiness, and severe headaches, with all the other symptoms of an acute meningitis, may at times usher in the disease. All these promonitory symptoms may be absent, and the disease may start in with a lethargica preceded perhaps for a few days by diplopia to which the patient pays little or no attention. The salient symptoms in the vast majority of cases are the drooping eyelids, the somnolence, the masked facies, and the rigid semiflexed extremities accompanied by a paralysis agitans tremor. These symptoms may be present in part, in their entirety, or in a varied degree. Many other symptoms or manifestations may be noted in individual cases. In one of the cases observed by the writer the patient presented a typical syndrome or Korsakoff's disease, together with diplopia and ptosis. The majority of the patients recover within a few weeks. The treatment is entirely symptomatic.

1. Lethargic Encephalitis.—Simon Flexner, after reviewing the history, pathologic and clinical features, and epidemiology, believes that, while waiting for the ultimate and convincing results of animal experimentation, one need entertain no doubt of the infectious and communicable nature of lethargic encephalitis. The belief that it is a communicable disease imposes certain responsibilities on the medical profession to limit its spread. The outstanding obligation is perhaps the close study of suspected cases in order to determine their real nature, meanwhile holding them under such conditions of isolation as is usual with this class of diseases. Every effort should be made to determine the existence of, and to detect and control the ambulant or abortive cases, having in mind that they may be more significant than the frankly lethargic and paralytic ones from the public health point of view. Since the nasopharyngeal secretions have become suspected of harboring the inciting microbic agent, adequate measures of controlling the distribution of these secretions into the surroundings of patients should be carried out. The physician should invite the cooperation of the bacteriologist and pathologist in attacking the unsolved problems presented by this disease.

5. Focal Infection and Its Relation to Obstetrics.—John F. Talbot, while not believing that focal infection is the only etiologic factor in the several complications of pregnancy which are here discussed, considers that it exerts a tremendous influence on obstetrics. Many complications, hitherto obscure as to etiology, can be attributed to the presence of a focus of infection. From a prophylactic point of view the obstetrician should study his patient to ascertain the presence of any such focus, removing it before it has caused trouble. The writer discusses the subject under two heads: 1. Complications which may be the result of a temporary bacteriemia or septic embolus; 2. complications which may be the result of the presence of the toxines of chronic sepsis in the blood of a pregnant woman.

2. Influenza as an Etiological Factor in Nephritis.—Thomson and MacAuley record the histories of four cases of nephritis following influenza and survey the literature of the subject. Their conclusions from the study follow: 1. That nephritis is a more frequent complication of influenza than is commonly thought. 2. That the virus of influenza may affect the kidneys in various ways: (a) by producing a temporary albuminuria, as seen in many other acute infectious fevers; (b) by causing an acute nephritis during the course of the disease, especially if respiratory symptoms are present; (c) nephritis may arise during convalescence, as in scarlatina; the damage to the kidneys may not become manifest until the patient is believed to have recovered from the original disease; (d) a dormant or latent nephritis may be lighted up. 3. Nephritis may follow even mild cases of influenza. 4. Nephritis occurring during the course of influenza may be masked by the respiratory symptoms, and only careful routine examination of the urine may demonstrate its presence, while some of the cases arising after the sypmtoms of influenza have abated may show such slight symptoms—transient edema, slight oliguria, or capricious albuminuria—that they may easily be missed. 5. That the urine in this disease should be frequeutly tested not only during the disease, but also during convalescence. 6. That probably the frequency and severity of the complication varies in different parts of the world in different epidemics. 7. That in the next few years we may expect in examination for life insurance to find a higher percentage of albuminurics.

2. Vertigo.—Sydney Scott discusses the surgical and medical treatment of vertigo under the headings, labyrinthine disease, Menière's disease, and unilateral Eustachian inefficiency. He sounds a warning against falling into the error of treating a possible infective labyrinthitis by procrastination, on the one hand, and, on the other hand, of treating vertigo impetuously by opening the labyrinth before ascertaining whether the signs justify a diagnosis of destructive labyrinthitis. Referring to the theory handed down by medical tradition that Menière's disease is due to hemorrhage into the labyrinth, the writer states that almost the only circumstance in which hemorrhage into the labyrinth occurs, and even then very rarely indeed, is that of leucocythemia in certain cases. The cause, he holds, often so subtle to find, and consequently so often overlooked, though admitted as the cause when recognized, is, in his experience, simply unilateral Eustachian inefficiency. It is when the tubes fail to open through some inefficiency, such as is produced by congestion or swelling of the mucous membrane due to a cold or catarrh, or when blocked by tenacious mucus or by temporary engorgement of the bloodvessels which supply the pharyngeal end of the tube, that the regulating action fails. A too tight collar in some is known to produce the same result. This mechanism is necessary because, as he has shown from laboratory experiments, a sudden change of pressure from low to high or high to low in the normal labyrinth on one side, or an asymmetrical change of pressure through the two sides, sets up temporary vertigo with nystagmus and other forced movements which characterize vestibular disturbances. Having scientifically excluded other factors, the treatment is directed to the Eustachian tubes.

Antipyrine Anaphylaxis.—Widal and Pasteur Valery-Radot report a case of anaphylaxis from a non-protein substance. Sensibilization, after having persisted for a long time, was succeeded by desensibilization. The patient, who was subject to attacks of migraine, took at the age of 24 her first dose of antipyrine and afterward continued to use it whenever she suffered from migraine. This status was maintained for nine years, at which juncture she developed the first symptoms of diabetes. Then for the first time a capsule of antipyrine caused a rash to appear, and this eruption reappeared after each successive dose. The rash was always of the same character and appeared at the same region—erythema and vesicles about the lips. Despite this disagreeable feature she continued to take the remedy until the age of 42, when by advice it was discontinued. She had taken the drug nine years without disturbance and nine years more despite the disturbance. She now went seven years more without a grain of antipyrine, but when admitted to the clinic for diabetes received a dose of half a gram. The rash promptly appeared exactly as before. Study of the patient showed the collateral phenomena of anaphylaxis—fall of blood pressure, marked leucopenia, and disturbances of blood coagulation. A number of other remedies were used to ascertain if an anaphylaxis developed with negative result, even pyramidon, so closely related to antipyrine, causing no disturbance. The dose of antipyrine was also varied and it was found that 2 cgms. caused the reaction in 50 minutes, while with a dose of 1 cgm. the result was negative. Antianaphylactic measures were now tested and after some weeks it was found that even a massive dose was unequal to causing the rash.

On the Proteolytic Enzyme of Fibrin.—Möllerström states that when ox-blood fibrin is thoroughly washed for a week in running water with chloroform addition it shows an increased proteolytic activity and when preserved in water or glycerin dissolves more readily than specimens less thoroughly washed. In 0.1 per cent. NCl acid albuminate is chiefly formed in fibrinolysis, but a genuine cleavage also occurs with formation of nitrogenous products which are not soluble in tannic acids or phosphotungstic acid. It is probable that enzyme action in sodium chloride solution has little or no significance for fibrinolysis. On the other hand, in an almost neutral fluid fibrinolysis is conditioned by the proteolytic enzyme present. A solution is prepared by preserving washed fibrin in glycerin with formol as antiseptic until the fibrin is almost completely dissolved. The gylcerin solution is now subjected to dialysis whereby a finely flocculent precipitate forms, and this also shows proteolytic activity. This precipitate is now filtered and it appears that the filtrate contains active proteolytic fibrin enzyme. In order to study the action of fibrin enzyme, weakly alkaline solution of casein is used as substratum; and in order to control the process of digestion tannic acid is used after a time to obtain a precipitate. In the filtrate the amount of nitrogen is determined by the Kjeldahl method. Research has shown that the proteolytic enzyme of fibrin acts best in neutral or very weakly alkaline media. Strong acids and alkalies hinder all enzymic activity. Chlorhydric acid is more active in the same concentration than acetic acid. The fibrin enzyme seems rather to begin a cleavage than to see one through, and it may be really a mixture of two enzymes.

SECTION ON MEDICINE.

First day—Tuesday, March 23.

JOINT meeting with the Section on Public Health and Sanitation.

Preventable Diseases of Adult Life.—Dr. EUGENE L. FISK, New York, presented this paper and showed statistical charts compiled from life insurance sources. Dr. Fisk said that one of the common diseases of adult life was old age, another was middle age. These were not limited to adult life. Old age due to syphilis might be acquired *in utero*. From that time on all stages of senility occurred, and in many individuals old age was reached during the period of youth. Physicians were too prone to label a patient as a case of this or that disease, or if a diagnosis was not possible, to dismiss the patient with a clean bill of health. To prevent old age or postpone it had seemed to many a quixotic proposition. Old age was always premature, and the physical changes noted in the advancing decades were not due to time but to an abstraction. Physical collapse, whether abrupt or spread over a period of 80 years, was the result of cumulative effects in the environment or in the individual. There were no pathological changes that were normal for any period of life. Factors producing old age were: hereditary (always influential); infections, acute or chronic by bacteria and parasites; poisons from within and without, including drugs; endocrine or other organ disturbances releasing poisons or interfering with their destruction; protein sensitization; hormone deficiency or excess; food deficiency, general and specific in lack of some special substance as vitamines or amino acids; food excess; physical trauma; physical overstrain; psychic trauma, such as fear, grief, and emotional distress which were more destructive than mental overwork; physical apathy—lack of muscular effort was justly charged with degenerative effects; psychic apathy this was the cause as well as the result of failing physical powers. Dr. Fisk made the following recommendations: More periodical physical examinations, more thorough teaching of diagnostic methods, diagnostic methods should be taught from the standpoint of finding out everything and not simply diseases; establishment in the industries of men of the type of medical supervisor for the supervision of industrial employees, and for inhabitants in general. We needed a department of health to coordinate all these activities, and we needed universal military training of young men between the ages of 18 and 21 in the form as it now stood in the bill before the Senate, so that the young men should be under strict medical supervision and be taught the fundamentals of personal hygiene.

Dr. A. W. FERRIS of Watkins, said that there was hardlv a medical matter of more importance than that in which Dr. Fisk and his coworkers were engaged. Our studies of disease should lead to one end and that was to increase longevity and have the individual lead his life happily. Our attention had been given too much to diagnosis and to combating disease. All some practitioners did was to write a prescription and have the patient call again. No directions were given as to hygiene, diet, habits, eating, sleeping, exercise, or diversions. The physician might say that he had not the time to go into all these details, but if he did not have time to give his patient justice he should refuse to see so many patients. Dr. Fisk had opened our eyes to the immense amount of scientific knowledge that was before us. We should always be on the lookout for infections, acidosis, toxemias from various sources, faulty methods of hygiene, too little ventilation, dietetic errors. He did not think we could benefit our patients more than by following these rules of Dr. Fisk.

Dr. L. F. BISHOP of New York City said that he thought that in criticising Dr. McKenzie and other heart specialists Dr. Fisk was laboring under a misunderstanding. What was misunderstood was the relation of murmurs more than the recognition of valvular defects. When a heart proved to be normal in outline with the orthodiagram and with the electrocardiagraph in every way except for the adventitious sound we were justified in saying that that sound was accidental. When we thought of the complicated nature of the inside of the heart, what a complicated chamber it was, the surprising thing was that there should not be adventitious sounds. That was what heart specialists meant—not to question the importance of valvular disease. Of course, we decried the harmfulness of making invalids of people with heart trouble by not taking these people into our confidence. Physicians did not appreciate the work that Dr. Fisk had done. Dr. Fisk had shown the importance of systematic periodical physical examinations and the whole question of health insurance was tied up in this matter, and unless the medical profession by perfecting their dispensaries and their hospitals and their work gave the public what the public was entitled to, the medical profession was going to have health insurance thrust upon them. The medical profession had got to do this work and not rely on outside corporations to do it for the public.

Dr. S. A. KNOPF of New York City, said that we were spending an immense amount of money for the cure and prevention of tuberculosis and still the most important point was neglected and that was early diagnosis. It was to this that we should look for the solution of the problem, early diagnosis was possible not only in the adult but in children. There were 66,000 men rejected for tuberculosis by the draft boards, and 25,000 men slipped through the draft boards and were found to have tuberculosis later. Only by the early discovery of tuberculosis should we be able to master this disease of all diseases.

Dr. R. H. HALSEY of New York City, said that in the campaign against preventable diseases of adult life the problem of preventing heart disease was greater than that of preventing tuberculosis. The rate of mortality (and morbidity) from tuberculosis in recent years had shown a decline, whereas in heart disease it had risen and more particularly in the type of heart disease known angina pectoris and in arteriosclerosis. The only way to combat this was to foster the idea of annual careful physical examinations of every individual, whether well or sick.

Dr. FISK, in closing, said that he did not wish to belittle the splendid work done by Dr. Bishop and others in the newer heart pathology. We should find out the quality of the circulation and not concentrate on the question of murmurs. If one read McKenzie's book, one would find a nonsensical criticism of life insurance examiners. The figures proved, however, that in men who showed nothing but a mitral murmur, the death rate was 50 points higher than normal. Of course, a man with a mitral or an aortic murmur could have his life prolonged; but McKenzie says, "dismiss that man, he can go about his business; there is nothing to it, inasmuch as he has no secondary change, he had better not be worried about his heart." The speaker's experience was that we had contributed to neurasthenias and phobias by not taking our patients into our confidence. We found that tuberculosis was on the decrease, but nine per cent. of the people examined showed some sign. Heart disease, as well as diseases of the blood vessels and kidneys were on the increase. Arteriosclerosis did not begin suddenly in old age. We should appeal for more autopsy work at each age period in order to have more microscopical and histological evidence of the changes in this disease.

Mechanism of the Compensatory Factors in Tuberculosis.—Dr. HARRY A. BRAY of Ray Brook read this paper. Dr. Bray said that a loss of lung volume necessitated a rearrangement of the thoracic organs. These rearrangements, more particularly in the advanced cases, were recognized by chest deformity, hypertrophy of the lung, and displacements of the mediastinum and of the diaphragm. There was an interrelation between these compensatory factors, and, depending on the impairment of one or more of these, the condition of the rearrangement resulted. This explained many apparent disparities in the physical findings, as revealed by roentgenograms. Upper displacements of the diaphragm, on one side or both, must be attributed to loss

of lung volume except in those cases due to pleurisy or to interference with the nerve supply. Where there was loss of lung volume on one side, there was migration of the mediastinum toward the affected side and elevation of the leaf of the diaphragm on the affected side. If the mediastinum was fixed, the elevation of the diaphragm would be greater, and vice versa, proving this interrelationship. The deflection of the mediastinum in some cases might be very considerable, and there might be an immense compensatory emphysema which would present physical signs hard to interpret, without the assistance of the *x*-ray. Where the mediastinum was fixed and the diaphragm also was fixed, what happened in these cases of extensive loss of lung volume was that the chest wall was crushed in with resulting deformity. Migrations of the mediastinum might occur to the right or left with equal frequency. Where the compensatory factors of the position of the mediastinum and diaphragm did not occur, the patient would develop a symmetry of the chest; but a patient with marked involvement might retain a symmetrical chest, so that the degree of chest deformity did not disclose the extent of loss of lung volume. In tuberculosis it was difficult or well nigh impossible to judge the extent, the nature, or the degree of the pulmonary process by asymmetry of the chest. In one old case with rigid chest walls the diaphragm and the mediastinum had not participated in the compensatory process and there was only one other factor left to compensate for loss of lung volume and that was hypertrophy or emphysema of the lung. Dr. Bray said that he had been teaching for a number of years that percussion and deviations in the respiratory murmur were not of very much importance, especially in early cases, for the detection of tuberculosis. It was possible for these compensatory rearrangements to become readjusted to their former normal positions after the progress of the disease had been arrested. In one case shown by the *x*-ray there was a difference in the level of the diaphragm on the two sides and widening of the intercostal spaces on one side; three years later with improvement in the condition, *x*-ray revealed the level of the two sides of the diaphragm to be normal, with return of the mediastinum, and a lessening of the width of the intercostal spaces.

Dr. EDWARD N. PACKARD of Saranac Lake said that compensatory emphysema in pulmonary fibrosis could lead to the erroneous diagnosis of tuberculosis; Dr. Flint had pointed that out following unresolved pneumonia. These nontuberculous conditions were more often basal, but were frequently mistaken for tuberculosis.

Prevention of Diphtheria.—Dr. W. H. PARK of New York City presented this subject. He said that no marked changes had been made in the medical treatment in the last few years. In the treatment by antitoxin we could come to use the single dose instead of the multiple doses. The use of antitoxin subcutaneously took two days for its full effect, while the use intramuscularly took still another day; with the intravenous dose the antitoxin passed out into the tissues immediately, whereas in the subcutaneous or intramuscular injection it remained in the tissues and diminished gradually for one to two weeks. So that treatment had come down to a single sufficiently large dose intravenously. Many physicians were not familiar with the method of giving an intravenous dose. In babies it was given in the jugular vein; in older children in a vein in the arm. Chills might occur after injection, but recently an antitoxin of high potency had been prepared and filtered so as to be perfectly clear, and in not more than two per cent. of cases had chills occurred. Chills did no harm, but were objectionable. The only cases in which they did not like to give an intravenous injection were those which had had treatment before. In those cases they feared anaphlactic shock. Where anaphylactic shock had occurred they had used adrenalin. Treatment had come to be more and more by intravenous injection in a single, sufficient dose. Dr. Park spoke about toxin-antitoxin injections and expressed the hope that they would eventually eliminate diphtheria. In 1893 cultures were first used for the diagnosis of diphtheria. It was then thought that, by better methods of reporting and by finding out the carriers, the prevalence would be diminished, but so far as statistics went that made no difference in the outcome of diphtheria. In 1895 antitoxin was used, and antitoxin reduced the death rate by two-thirds. Antitoxin, being made from the horse, was foreign to the human organism and did not remain in the body for more than four weeks, so that at the end of that time injections had to be repeated. We still had a remainder of about one-sixth of the deaths and two-thirds of the cases per 100,000 people, and there it seemed to remain, as carriers in great cities existed to the number of three per cent. and were all the time changing, and more than half of the cases developed from unknown carriers. We must remain at this point or find a method of active permanent immunization. In the use of toxin-antitoxin we had a method of procuring this. Formerly it was necessary to bleed to find the immunes and nonimmunes to whom this should be given, so that until the Schick test came the matter remained as an experimental study. Behring was the first one to use this practically, but his work had been cut short by his death, and the whole European work was cut short by the war so that it left this country to go on with it and watch results. The value of this work depends on the Schick test. The Schick test was the injection intracutaneously of a small amount of the toxin so that it remained in contact with the cells. If no local reaction occurred, the individual had sufficient antitoxin in his body and was immune to diphtheria—negative Schick test. This was particularly true in infants and young children. In older people we might find that some toxic substances in the broth injected caused a pseudoreaction; with practice most of these pseudoreactions could be determined, as by injecting the broth heated and unheated. Dr. Zingher had found from studies on children extending over years that in only three per cent. of the children did a negative Schick test change to a positive test. So that a negative Schick meant an immunity for years, and Dr. Park believed for life. Occasionally there were gross discrepancies in the Schick test, and we knew that these must be due to imperfect toxin or methods. A negative Schick test meant that the individual had antitoxin and was immune to diphtheria; a positive test did not necessarily mean that he was susceptible. There were cases that recovered from diphtheria and after recovery showed a positive reaction. The Schick test enabled us to find who were immune. Infants, we knew, obtained their immunity from their mothers, and from infancy on to two years this immunity passed out, so that the greatest number of nonimmunes occurred in infants between the second and third years, and from then on the percentage of nonimmunes grew less as ages advanced. They used the toxin-antitoxin mixture on the nonimmunes. This mixture grew less and less toxic month by month so that if it left the laboratory carefully tested, it was as safe as any product could be, as the product never became unsafe if it left the laboratory safe. This product had strong immunizing properties, and had been given to infants of one week old in full adult doses and with no deleterious effect. After one injection 70 per cent. would be immune at the end of one month; two injections would give about 90 per cent. of immunes, so that by reinjection we could bring most of the nonimmunes into the immune fold. How long did the immunity last? After investigations for four years and a half Dr. Park said he believed that the immunity conferred was permanent. Babies stood these immunizing doses better than adults and older children in whom more marked reactions occurred with rise of temperature, prostration, etc. So that he felt that the babies between six months and two years should be the ones to be immunized. He believed that we could get an immunization of the whole infant population, that the method was entirely harmless and that it gave permanent immunity that would eliminate diphtheria.

Dr. SAMUEL A. BLAUNER of New York City reported the occurrence of eight cases of diphtheria in an infants' asylum in New York, which was very difficult to explain. In the asylum in question it was the custom to apply the Schick test to all infants and to immunize the positive reacting ones with toxin-antitoxin. In a ward in which all the children were supposed to be immunized there developed three cases of sore throat, which by culture proved to be true diphtheria. On the

appearance of these cases antitoxin was given, but five other cases developed. The question was whether we were dealing with diphtheria carriers who at the time happened to contract streptococcus sore throat. These cases were given the usual dose of antitoxin and their throats again cultured, and the cultures were negative, showing that they must have been cases of true diphtheria. These cases had shown a negative Schick reaction. Now the objection to the fact that these cases were diphtheria was the fact that possibly they were cases of streptococcus sore throat, but against that were the character of the local symptoms, the fact that the children did not have the sepsis of streptococcus sore throat, and finally, if these children were carriers, then why were those throats negative after the local symptoms had disappeared? We had a case of a child who refused to be immunized, yet this child possessed virulent diphtheria germs in his throat, and in spite of the fact that we had an epidemic of diphtheria in the wards, he did not contract clinical diphtheria.

Dr. S. B. Howe New York reported his experience with the Schick test in an institution in New York. They began using the Schick test in May, 1906, and immunizing all positive cases and had no diphtheria up to the present time, except for a short period when they immunized only, not using the Schick test. He felt certain now of the value of the Schick test and was very watchful to see that it was carried out in the proper way, as instructed by Dr. Park.

Dr. H. N. Appel of New York City said that he was on duty at the asylum where the cases mentioned by Dr. Blauner occurred, and that he would like to add something that perhaps Dr. Blauner had forgotten. In one of the group of children in the ward where the child came down with diphtheria the children were promptly immunized and not a case of diphtheria developed. That tended to bear out the assumption that it was diphtheria, because if it had been a case of streptococcus sore throat, immunizing the children would not have had any effect in limiting its spread.

Dr. Kling of New York City said that he would vouch for the reliability of the Schick test, if properly carried out. In a series of 2,000 cases with negative Schick test who were exposed to diphtheria not a single case developed. None of these children received an immunizing dose of antitoxin; but to be sure that one could depend on the results, one must be sure that the material was right and that the methods were right. In an institution where the work had been carried on for two years, the negative reactions became positive.

Dr. Park, in closing, said that he had investigated the occurrence reported by Dr. Blauner, which was most difficult to understand. To his mind it meant that the negative Schick-tested children and the toxin-antitoxin injected children developed diphtheria but that the children who had naturally a negative Schick by their own antitoxin did not develop diphtheria. When he first investigated the cases one child was coming down with a sore throat, as mentioned by Dr. Appel, and he suggested that if they were willing to take the risk and not treat this child with antitoxin it would show the same history as the other children who were given 1,000 units. This child with tonsillitis did recover in the same way, though it received no antitoxin, as the others that did receive it. There was one case with a negative Schick, but it had passed away in that time. He knew that antitoxin in the body will disappear, and that is the reason he wanted to use active immunization. Now as to the diagnosis: one could not tell a tonsillar diphtheria from any other form of sore throat. There must be some kind of tonsillitis with virulent bacilli on the patch, but whether the diphtheria bacilli added anything to the local signs on those tonsils, we did not know. We did not know whether if we had a streptococcus sore throat in a diphtheria carrier it would or would not have some effect on the mucous membrane of that tonsil; it might be free on the outside. That was a question we could debate for ever; but he did feel that there was no reason possible for diphtheria poison to cause constitutional symptoms if there was antitoxin in the body, and he believed the toxin made by the patient and that made by the horse was the same. If the Schick test properly done did not prove that, then our reasoning was wrong.

The Tonsils and Scarlet Fever.—Dr. E. H. Place of Boston read this paper (by invitation). Dr. Place said that he could not help reflecting on the fact that this was one of the diseases in which modern science had added practically nothing in the way of diagnosis or treatment. In the realm of treatment possibly with the utilization of antibodies which had been produced in other human beings no marked improvement had been made. In searching the problem for some point of attack, he could not resist the temptation to speak of this subject of the relation of the tonsils. It was interesting to note that the tonsils were the first point of localization, and that in all cases associated with death they were affected, and this was the case in other infections such as endocarditis. But nothing definite was known as to the relation of the tonsil to the portal of entry in scarlet fever, on account of the difficulty of human experiment. Animal experiments had suggested this as a possible portal. The difficulty of recognizing the disease as scarlet fever where disease had followed inoculation of the throat with scarlet fever made such experiments of doubtful value. Berger and others had observed scarlet fever coming on after wounds, surgical operations, and in the puerperium; in these cases the mildness of the throat symptoms had been noted. In 30 cases in his wards there were only three that had very marked throat symptoms, and in all of the cases in this group the throat symptoms became appreciable after the first appearance of the rash—quite a distinct contrast to the ordinary course of scarlet fever. It was difficult to make the diagnosis in these cases of scarlet following an operation wound; cases of this kind were apt to have a rash due to other causes. However, in his series most of the cases admitted to his ward had been in contact with patients with scarlet fever, and in none of them had a new attack of scarlet fever resulted. On the other hand, one might have throat symptoms so mild in scarlet fever as to throw doubt on the diagnosis. The speaker's practice was to accept as scarlet fever only those cases that had throat manifestations, and to reject all in which the throat was normal. Another point in relation of the tonsil to the etiology was that the faucial ring and the tonsil were the first point of attack in this disease, and this fact was accepted as the first sign of scarlet fever. The lymphoid tissue was the one tissue that showed pathological changes in all patients that died, and the hyperplasia of the lymph nodes to which attention had been drawn by Shamberg was seen in other exanthemata. Another fact that seemed to point to the tonsil to prove its etiological relation to scarlet fever was shown in epidemics of milk-borne scarlet fever. In epidemics of that disease the proportion of cases in adults had been noted to be always high. Of course, it was impossible to say how much the stomach or intestines had to do with these milk-borne cases. As to relation of the tonsil in scarlet fever to the secondary and septic infections, septic sore throat occurred chiefly in patients who had large tonsils—in fact 65 per cent. of the cases showed large tonsils. In a series of cases of septicemia all had enlarged tonsils. In a series of cases of acute nephritis none had had tonsillectomy. Besides this evidence we had the relation of tonsillectomy to the complications and the clinical course. It had been noted repeatedly that in cases in which tonsillectomy had been performed, the throat symptoms were extremely mild. In a large number of these cases the speaker had records of only three in which there was marked or severe throat involvement. As an interesting or side light on this point he had had the good fortune to see six cases in which the tonsil had been removed on one side; and in these the contrast between the side on which the tonsil had been removed with the other side was very marked. Indeed it was in connection with this that he was intending to advise the removal of the tonsil as a prevention of scarlet fever. In acute cases tonsillectomy could be performed with good results.

Nationalization of the Agencies for the Health Welfare of the People.—Dr. Albert T. Lytle of Buffalo read this paper. He thought that some form of government subsidy would have to be devised to secure the requisite number of practitioners of medicine of the proper standards. There were only 35,000,000 people in the United States classed as healthy, and only 19,000,000 people in full vigor. There were a great num-

ber of fake health measures offered to the public, and illogical and unscientific health cures which succeeded even in the face of greater requirements of those practising medicine. Cooperative insurance under government control had not solved the problem for the advancement of health conditions. Any measure that had compulsory features was liable to fail. Individual health welfare service was needed; also a State Department of Health to manage and control health institutions, hospitals, and dispensaries, and compulsory periodical medical examinations of all individuals, the individual to have his choice of examiner, each individual to be taxed.

Dr. KIDDER said that he happened to be on the committee on health insurance, and he came to realize the little knowledge that physicians in general had about the scope of the measure and its effects. Practice and medical requirements were changing. The physician was not needed for emergency work alone, or to attend patients to whom he was called. The physician's work was changing to elective work. Dr. Kidder showed conditions of practice in one county in the State having a population of 72,000 in which there were 69 physicians, and summarized the conditions of practice in that county, which were not creditable. He did not wish to criticise the raising of the standards of medical education, but thought that the changes made were too revolutionary, they should be evolutionary instead. In this tread toward State medicine we should see that it was not forced on the medical profession from the outside. Dr. Kidder emphasized the fact that papers like that of Dr. Lytle should be taken more seriously by the profession.

Second Day—Wednesday, March 24.

SYMPOSIUM ON VITAMINES.

Joint meeting with the Section on Pediatrics.

Fat-Soluble Vitamine A.—Prof. LAFAYETTE B. MENDEL of New Haven read this paper by invitation. In 1881 Voit wrote that it would unquestionably be best to feed only pure chemical compounds, for example, pure protein, fats, sugars, and ash constituents, or mixtures of the same; but as men and animals rarely tolerate such tasteless mixtures, it was necessary to feed food stuffs provided by nature. To Professor Hopkins of Cambridge University, England much credit was due for his researches in foods and vitamines. The report of the Lister Institute in England should be read by those interested. It was assumed that more than one accessory factory in the diet might become responsible for deficiency diseases. Scurvy was one of these, and its cure depends on antiscorbutin; beriberi was another and it might be cured by small quantities of yeast which contained the antineuritin. Yeast was strongly antineuritic but was not antiscorbutic. Flavor was not the factor that was involved in these cures. Professor Mendel described his experiments of feeding animals (rats) on a diet deprived of the fat-soluble vitamine by prolonged extraction of the foods with alcohol and ether, and then feeding various substances to supply this fat-coluble vitamine. It might be said that this vitamine was present in fats derived from animal tissues and in roots and tubers, but was missing in purified commercial vegetable oils. The oily residue in spinach was comparatively rich in fat-soluble vitamine. In feeding animals on a diet free from fat soluble vitamine the symptoms noted were a loss of weight or a failure in normal growth; sometimes the loss in weight was sudden, similar to the decline in malnutrition in children. Another very common and striking feature was a condition of the eyes known as xerophthalmia, the precise nature of which was still under observation. These changes were found in rats on a diet devoid of fat soluble vitamine. Bacterial invasion was not a cause of this condition. Animals in unfavorable physical condition, not deprived of fat-soluble vitamine, did not develop this condition. Another abnormality encountered at autopsy was the presence of calculi in the bladder and ureters. These calculi were composed of calcium phosphate and attained a large size. More recently the rôle of the fat-soluble vitamine as an antirhachitic had been brought into consideration. These was abundant evidence that water-soluble B was needed throughout life. In the case of fat-soluble vitamine the indications were that it was needed particularly in the early stages of life. Full grown rats might be kept in health on amounts that did not suffice at an early age when growth is rapid. Inasmuch as butter fat had been employed as a source of this food factor, comparisons could be made. About one-tenth of a gram of butter fat per day in connection with an otherwise adequate diet served to keep the animals (rats) in health. With a tenth of a gram of dried spinach the results were equally favorable. Even more striking had been the results obtained with dried tomato, which served as the source of fat-soluble vitamine for fourteen months. This vitamine might bear some relation to pigments; thus white potato was comparatively poorer in it than carrots or spinach. The question of the stability of fat-soluble vitamine had been the subject for debate. Butter fat through which live steam had been passed did not lose its validity. Others had said that it was destroyed by heat, but the speaker had found it still potent after heating. The vitamine in liquid butter oil was very stable. In the hydrogenation of oils the vitamine was destroyed. The antiscorbutic factor was more susceptible to disturbance by heat than others. It had been demonstrated that heat applied in the sterilization of food might destroy or diminish the antiscorbutic vitamine. Unfortunately this fact had been subjected to broad generalization with respect to all foods. It was known that orange juice and tomato juice were very stable. The wide distribution of water-soluble vitamine seemed to render the possibility of a deficiency of this vitamine less likely to occur than that of fat-soluble vitamine. The success of the Danish people in nourishing themselves in the latter years of the war was due to the abundant intake of plant foods supplying the missing factor. It needed to be emphasized that these vitamines had not been isolated. In view of this fact men interested in diets should beware of false statements in regard to the claims of nostrums alleged to contain vitamines.

The Antiscorbutic Vitamine.—Dr. ALFRED F. HESS of New York read this paper. In the days of long voyages, he said, scurvy constituted one of the greatest plagues in navies. It must not be thought that because trips were shorter and we had refrigeration that scurvy was a thing of the past. It had merely changed its form, and in the world war scurvy was by no means absent. In the latter part of 1917 the British had many cases of scurvy in their colonial troops in Mesopotamia. Russia and Roumania were afflicted with scurvy after their defeat by the Germans. Scurvy had changed and now presented itself in the latent form. It might occur in patients suffering from fever or in patients suffering from gastro-intestinal disease whose diet had been limited. However, scurvy was more particularly a disease of infants, of artificially fed infants. This disorder was important not merely for itself intrinsically but it led to other diseases, for instance, it was found in this war that those who had a lack of the antiscorbutic factor were more subject to pneumonia and succumbed to it, and that in wounded soldiers the wounds healed less rapdily. Diseases which ordinarily showed a slight petechial rash, as meningitis, might show a hemorrhagic rash in a patient suffering from scurvy even in latent form.

We know little about vitamines in general, but we knew more about the antiscorbutic vitamine than others. We knew that it was soluble in water and in alcohol. It was the most sensitive of the vitamines to heat and drying. There was no evidence that the antiscorbutic vitamine could be stored us. In an experiment on guinea pigs in which one group was given a minimal amount of orange juice and another group twice that amount, and then both groups fed on a diet deprived of the antiscorbutic fact, both groups developed scurvy in the same length of time. In other words, those that got the two-fold dose were not able to avail themselves of the excess. As to the function of the vitamines: the antiscorbutic vitamine seemed to be needed for the endothelial cells of the blood vessels, and if there was lack of this vitamine, the blood vessels gave way and hemorrhages occurred which were

characteristic of scurvy. This was subject to experimental test, for instance, if one bound the wrist in a case of scurvy, the congestion would lead to a large number of petechial spots on the forearm. In other words, the blood vessels were unable to resist the increased pressure; after administration of orange juice this test would result negatively. Other cells were not so sensitive to lack of this principle. We knew that infants suffering from scurvy gave a negative Schick reaction. As regarded the presence of this vitamine in the various food substances it was contained mainly in vegetables and fruits, oranges, lemons, cabbages, and onions were particularly rich in it, whereas apples and beets were poor. Then the amount varied in the same vegetable, new carrots contained more than old. We could not frame a table with any degree of accuracy. The British commission had said that drying destroyed the antiscorbutic principle in food stuffs; they had said that all dried food stuffs were deprived of antiscorbutic value. Although this was true in general, there were exceptions. In the laboratory tomatoes, cabbages, and oranges had been successfully dried. On the other hand, we must consider, that dehydrated vegetables as prepared commercially had no antiscorbutic value. Dried milk, if properly prepared, had antiscorbutic properties; of course, the milk to be of value must originally have possessed these properties. Milk must be quickly dried and sealed soon after, hermetically. Dried milk could retain antiscorbutic properties for three months. He did not mean to say that it was not advisable to give antiscorbutic food with dried milk, but he brought this forward to show that milk could be dried and still retain its antiscorbutic properties. The same was true of canning, though canning, as might be expected, usually destroyed the antiscorbutic properties, yet there were exceptions to this rule. As Dr. Mendel said, acids particularly preserve and protect the antiscorbutic vitamine, they protect it against heat and drying and canning, and therefore we found that canned tomatoes were very rich in antiscorbutic properties, partly because they were acid and partly because they were put in a sealed container. The question of the access of air to food stuffs was of prime importance. Foods lost their antiscorbutic properties on exposure to air. The speaker did not believe that there was any more valuable antiscorbutic for the prevention and cure of scurvy than canned tomatoes. It was cheap, was well borne, and was available. The tomato was given, just strained, as it was taken from the can without any previous heating and given in doses of one ounce to the youngest babies. As regarded milk, pasteurization impaired or diminished the antiscorbutic property but did not entirely do away with it. Babies that were nursed did not develop scurvy, it was only the artificially fed ones that did. There was no reason to believe that human milk was any richer in vitamine than cow's milk. Six ounces a day of mother's milk was found insufficient to cure scurvy. It was known that it took about 16 ounces of cow's milk to cure scurvy, so that the antiscorbutic content of human and cow's milk was about the same.

Water-Soluble Vitamine B.—Prof. THOMAS B. OSBORNE of New Haven presented this paper (by invitation). He said that the effects of diets free from this vitamine had convinced us that this vitamine was essential for all animals, but no records existed to prove it was essential for man. In the past the deficiency features of food poor in vitamines and their effect on man and animals had chiefly interested investigators. Dr. Osborne wished to say a word about the stimulation of metabolism by vitamines. In such experiments the calorimeter must be resorted to. Food intake was a proximate measure of the animal's metabolism. Under natural conditions normal animals, including man, adapted their consumption of food to their need in calories. It was plain that each ingredient needed would be eaten in sufficient quantity. Under those circumstances food intake indicated vitamine intake. Long continued maintenance in a general state of debility followed the ingestion of food low in this vitamine. If the vitamine intake was increased appetite at once returned, and unless during the period of debility the animal had contracted some infectious disease, or suffered from organic change, it was rapidly restored to health and vigor. This could be attributed only to a stimulation of the metabolism. It was the administration of the vitamine that caused recovery, not the amount of food taken. There were individuals who lived for years with a correspondingly low food intake. It was probable that the poor appetites of these individuals was due to the small amount of vitamine they took in. If this surmise was correct, they should be improved. Those men and women who ate habitually too little food might require more vitamine than the average dietary supplied. A large part of the food of the American was deprived of vitamines, thus sugar, flour, and rice in their preparation were deprived of these substances. No great harm, as a rule, resulted because we ate other food substances and obtained the proper amount. In feeding people whose metabolism was low and whose intake of food was small, we should not supply too many calories without vitamines. For example, this was done in convalescence where the physician furnished fruit and restricted the amount of rich food. Too little scientific investigation heretofore had been given to the phenomena of the planes of metabolism of different individuals, as in the active individual compared with the lethargic one. What was meant by the power of recuperation? By obesity? These conditions mostly concerned metabolism, and with them the physician frequently dealt by prescribing sedatives. Possibly these conditions depended on the stimulation of vitamines. It might help in prescribing diets in special cases to know what had been recently learned as to the sources of water-soluble vitamine. Dried brewer's yeast was rich in this substance. Yeast was not now available. The physician would naturally prefer to employ some food product. Dr. Mendel and the author had shown that oranges, lemons, and grape fruit were rich in water-soluble vitamine, apples and pears furnished less, and bananas still less. Among vegetables some had a large content such as tomatoes, cabbage, and onions. Among animal foods milk, eggs, liver, kidney, and heart contained the most water-soluble vitamine, while meat and fish contained less. Yeast consisted of nucleated cells and was richer in purin bases than almost any other food product. Yeast should not be used where purins were contraindicated. Yeast had been prepared free from purin derivatives, and that used with good effect.

Dr. E. V. MCCOLLUM of Baltimore said that there was very little that he could add in regard to each of these three dietary essentials which all now agreed were indispensable in the diet of man. He was in accord with everything that Dr. Hess has said about the antiscorbutic substance and could add only one thing which he thought he inadvertently omitted and perhaps was worth mentioning, namely, in the Lister Institute in London they had found that during the germination of seeds there was a marked increase in their content of vitamines. Dried grains were almost valueless in the treatment of scurvy, but if the same grains were sprouted they immediately developed antiscorbutic properties. Muscle meats, which had been mentioned in the discussion, had been shown to have almost no protective action against scurvy. Furthermore, the experience of all was that the muscle meats were poor sources of all three of the recognized dietary essentials which were concerned in the etiology of the specific deficiency diseases, scurvy, beriberi or polyneuritis, and xerophthalmia, if this latter had ever occurred as a deficiency disease in man. There was no doubt in his mind that Dr. Mendel's statements about the stability of the fat-soluble vitamine was true notwithstanding the statements of other observers that it was destroyed by heat. Now he wanted to call attention to a difficulty which would show why there existed honest differences of opinion about a matter which would seem to be easy of demonstration; namely, did a sample of butter fat lose its antiscorbutic value when heated for varying lengths of time? He would call attention to the difficulties one faced in solving a probolem of that sort. If one took rats of 50 grams body weight and placed them on a diet which was free from this substance but satisfactory in all other respects, and then waited for them to develop xerophthalmia and then proceeded to cure them after they had developed this pathological condition of the eye by cer-

tain doses of butter fat or other food substances, one would find that there were no standards by which the pathological condition could be measured—the condition of the animal would vary markedly, and the effect of different substances in the cure of this condition was subject to marked variations dependent on the interpretations of the investigator. The difficulty in this field was that workers were not all trying to do the same thing, there was no standard of procedure. A point of considerable importance was that we must not lose sight of the fact that, however interesting these substances concerned with the etiology of deficiency diseases might be, they were not the whole story in nutrition and dietetics. There were other factors equally important. Dr. Mendel and Dr. Osborne had made comparisons of the biological values of proteins from different sources, and we know that the proteins from certain vegetable products were more distinctly lower in biological value than the proteins of other foods, notably milk and eggs. We should appreciate that combinations of food were indispensable to the making of a proper diet. To determine accurately the value of a given diet in an experimental animal, in a rat, for example, it was necessary to study the complete life history of the animal. A rat might grow to maturity normal to all appearances but might then undergo a rapid decline, or might be unable to reproduce young or to nourish its young. If the experiment were not continued longer, such a rat would be regarded as a normal rat, and no fault in its diet would have been discovered. It was only by prolonged observation that defects in diet might be discovered, even observation of several generations might be necessary to secure a complete biological analysis of a food stuff, and it was only in that way that we could find the proper way of supplementing our natural foods by combining them to get the best results. A very important point in nutritional experimentation was brought out by this type of experiment, namely, by modifying a diet in different ways we could determine at will the length of that period which followed the attainment of full growth. In this way we could detect minor differences in the value of a diet. There was no reason to believe that we ran anywhere near the danger line in the diet of the average American citizen who was free to make his choice as to diet. It was still another question whether the inmates of an asylum or a prison or orphanage did not run too short on at least one of these unknown vitamines. He had had an extremely interesting experience in improving the diet in an orphanage in Baltimore. There was a group of negro children in an asylum where the surroundings were excellent, yet not a single child in the group was normal. It was apparent that the nutrition of these children was far below what it ought to have been. The food intake and diets of the children were investigated, and it was found that they were fed entirely on a diet of bread, corn meal, and other cereals with vegetable soups made largely from rice, peas and beans, and meat. It was essentially a seed, meat, and tuber diet from the products that were on every grocer's shelf. Upon adding fresh vegetables and dairy products, milk and eggs, to the diet there was a very marked and striking improvement in the condition of the children. There were very few people who realized that a diet of meat and bread and potatoes was not a satisfactory diet, it could only be made so by the inclusion of leafy vegetables and dairy products. One could not overemphasize the importance of putting these products into the diet to correct deficiencies in the diet. Of course, it was a very difficult problem in many instances to decide whether deficiency existed, and there was abundant reason why different investigators arrived at different results, their methods not being exactly alike.

Dr. Casimir Funk of New York said that he subscribed to everything mentioned in the discussion and to the explanations of Drs. Mendel and Osborne. With regard to a few things that required special attention: first, the number of known chemical vitamines was exceedingly small. We know very little about the fat-soluble vitamine; we did not know whether it contained nitrogen or not. We knew very little about the antiscorbutic vitamine, but that perhaps it might be derived from germination. According to one experimenter, as the antiscorbutic vitamine increased the antiberiberi vitamine decreased; that might be a proof of transformation. At present we did not know much about the chemistry of vitamines. He thought the antiberiberi vitamine belonged to the purin group. He was glad to know that Dr. McCollum accepted the three vitamines, and it would be advisable for us to keep the situation open, as many other vitamines might be found yet.

Dr. L. Emmett Holt of New York said that it was a very happy thought of the chairman to bring together in this meeting the laboratory workers in the country who have contributed so much to the subject. He thought it was well known to every one who had studied the question at all that the best work which had been done in the world on the subject of vitamines and laboratory feeding had been done in the laboratories of this country. He had visited the laboratories of Drs. Mendel, Osborne, and McCollum. Of course, it was possible for them to do with their patients what we could not do with our children. Of course, their patients had no relatives, and of course they had no difficulty in obtaining autopsies to see what the results of their feedings had been. They could control their conditions, and they had contributed a great deal to the understanding of the problem of nutrition, and had shown how progress along these lines would be accomplished. Nevertheless we must be careful in carrying over into human practice the conclusions derived from animal experiments. One thing that impressed him was the widespread occurrence of these substances in our common foods. It was the patient who had come to restrict his diet to a few things who suffered; it was the child who had been fed on an exclusive diet who got into trouble from the lack of special vitamine. The person who ate our common food in abundance in its natural state got an abundant supply of these natural vitamines. The tendency at the present time was not to let well enough alone; our foods were continuously purified for use without being improved. Milk was pasteurized and foods were dried, and we had got into the habit of eating these foods so that the danger of deficiency diseases was increased. He thought the lesson was that we should eat a variety of foods and not limit ourselves or our children to a narrow diet. One of the things that had impressed him was that the child should be taught to eat the proper food. We saw the whims of the child catered to by parents who gradually took one or more things away from the child's diet. Dr. Holt said that pediatrists realized the importance of a general diet for a child and would not allow a child to restrict his diet to a few things unless he was carefully watched. We heard about milk being the perfect food. It was not, even for the calf. The calf was born with eight teeth and ate grass immediately after birth, and nature did not intend him to live exclusively on milk; and we saw great harm done to children who were living on an exclusive milk diet and were refused other foods. Now in all these deficiency diseases the one that concerned us most was the antiscorbutic vitamine, the absence of which produced infantile scurvy. The speaker had been interested in finding out how long it took to produce scurvy. Scurvy could be produced in a guinea pig in 18 to 20 days, and death would occur in five weeks. A monkey that was fed on a diet that contained no antiscorbutic principle would develop scurvy in three months. How long did it take a child fed on pasteurized milk to develop scurvy? How soon was it essential to give antiscorbutic vitamine to a child fed on pasteurized milk? The speaker had two infants who were fed on pasteurized milk with only cereal additions; in one of these infants scurvy developed at eight months. We knew that the pasteurization of milk did not destroy the antiscorbutic vitamine, it only impaired it; and pasteurized milk had less of the antiscorbutic vitamine than raw milk. Of course, the condition of the infant fed on pasteurized milk was not parallel to the condition of the animal wholly deprived of antiscorbutic vitamine. Apparently an infant who was getting pasteurized milk as its chief source was not likely to develop symptoms until somewhere between the eight and ninth month. Consequently he thought it safe to practice to make that infant at six months have some antiscorbutic vitamine,

and this should be given as a regular part of the diet at six months. Now with reference to some of the antiscorbutics: Dr. Hess had spoken of tomato juice, that was certainly the cheapest for hospital, dispensary, and institution practice. Patients in the dispensaries had found tomato juice as expensive as orange juice. If a ten grain powder of benzoate of soda was added to a pint can of tomatoes, it would keep until used up. Tomato juice could be given freely to infants six months old and in the same dose as orange juice with beneficial results in the prevention and cure of scurvy. He had been interested in the effects of dried orange juice. The process was that used in the drying of milk, viz., spraying into a hot chamber. In one case he cured scurvy promptly with orange juice that had been dried a year before. Apparently the drying of orange juice did not impair its antiscorbutic properties, and apparently the keeping of orange juice for long periods of time did not injure it either. As far as the other vitamines were concerned, it seemed that children were sure to get enough of them unless they belonged to families where children had their own ways in matters of diet; except for that he did think we were apt to see trouble from the lack of fat-soluble or water-soluble vitamine. Of course, we realized that milk was the diet for children, and if milk were given freely, the fat-soluble and the water-soluble vitamines would be taken care of.

Dr. GRAHAM LUSK of New York said that in England one of the publications that was mentioned by Dr. Mendel stated that wherever general debility occurred in a mass of troops a dietetic deficiency should at once be suspected. That was a very important enunciation. It was only five years ago that there was published from the speaker's laboratory an analysis of the calories in the food at the Childs' restaurants. They had found that the calories in tomatoes cost about as much as to calories in champagne, that the tomato was practically flavored water colored red; and since that time through the researches of Dr. Hess they had found that it contained a valuable fat-soluble vitamine. We were advised to take milk. It was quite right. Why did people take meat? What was meat? It was still perhaps to be defined. Dr. Osborne has suggested that part of the specific dynamic action due to the ingestion of meat, namely, the increase in metabolism, was due to the presence of amino-acids, but it might be in these depleted animals that there was a lifting of the metabolism to a higher plane. It seemed that the science of nutrition should be more known and realized. One quarter of the income of the country was spent for food. Fifteen per cent. of the population were farmers and they were represented by a department at Washington, the Department of Agriculture, while the other 85 per cent. of the population were not represented by a department of public welfare. Why should we not have something such as was recommended by the Allied Food Commission? He was glad to say that they were going to establish in Amsterdam a research laboratory which would also have a department for propaganda through newspaper control. We did not want newspapers written by outsiders who would exploit these things; we wanted the right kind of propaganda such as had been presented here to-day.

Dr. E. C. VAN LEERSUM of Amsterdam, Holland, said that he was here in this country visiting several laboratories in the field of nutrition and was in search of information for the organization of the Institute in Amsterdam, which, as Dr. Lusk said, would have a department of research, a department of information and statistics, and a department of propaganda.

Dr. MAURICE J. LEWI of New York said that the vitamines reminded him if the old opsonic theory. Until we knew more about the chemistry of these undiscovered substances we would be at sea. The speaker had found through clinical experience the value of the methods which had been suggested in rendering a cure of a child who was scorbutic or rachitic. It would be a crime against the profession for anybody to attempt to exploit anything in the way of a medication to take the place of the natural foods containing vitamines.

Dr. MENDEL said that for the present we should obtain our vitamines at the grocery store and not at the drug store.

Dr. HESS said in regard to germinating seeds developing antiscorbutic properties that they did not have any practical value in treatment, as shown by the British Commission. They could not be given raw, and when cooked they lost the larger part of the antiscorbutic properties. At present it would seem that onions would be one of the best things for armies, and even better would be the dried orange juice mentioned by Dr. Holt, which was in small bulk and would keep. As regarded the antiscorbutic value of meat muscle, from a quantitative point of view it no doubt had value as shown by the experience of arctic explorers who subsisted wholly on meat. As to the time it took to develop scurvy in infants on pasteurized milk, Dr. Holt put the time at eight months, but it would seem better to start antiscorbutics earlier, at say the third or fourth month or even earlier.

Dr MCCOLLUM said that the remark about meat applied solely to muscle meat. The glandular organs, such as the liver, kidney, heart, and pancreas, were eaten freely by people in the arctics; that was a different thing from muscle meat. One could cure scurvy very promptly with very small doses of liver.

SYMPOSIUM ON ENDOCRINE DISEASES.

The Relationship of the External Appearance of the Body to Disease.—Dr. GEORGE DRAPER of New York read this paper. He said that in 1916 he was impressed with the strong resemblance of the individuals who were affected with acute poliomyelitis. In families where one child was affected, the appearance of the child was different from that of the other children. What the relation to susceptibility was had not been determined. The same observation was made in the army in respect to epidemic meningitis. In the study of susceptibility to infectious diseases we still lacked the key to the situation. One man in a tent would succumb and the others escape. Among patients sick with the same identical strain of microorganism, one would die in a few hours and the others recover. Was there any relation to susceptibility? Breen had classified the human race according to the length of the intestine, and Goldthwaite divided human being into the carnivorous type and the herbivorous type. There was no standard type to which anthropologists could apply the term of normal. The relationship between certain pathological states of endocrine glands and the appearance of a man might furnish a clue which might be used in analyzing the differences in personal characteristics. As a sort of plan to work on, individuals might be grouped in four panels—anatomy, physiology, psychology, immunity. The relation of the endocrine balance to these four panels determined the characteristics of the individual. This was hypothetical, and, of course, all four of these panels interlocked and worked together. The probability of this matter of the external appearance of the body to the endocrine glands gave a new impetus to this study of susceptibility.

Disturbance of Internal Secretion of Sex Glands.—Dr. WILLIAM C. QUINBY of Boston read this paper (by invitation). Dr. Quinby discussed the clinical and experimental evidence of the function of the gonads, that is, the sex glands in either sex, and showed instances of disturbed function of those glands as regarded their endocrine function. The testicles and ovaries were organs in which were formed spermatozoa and ova, which might be considered as analogous to the external secretion of other glands of the endocrine system. The gonads, the testicles, and ovaries had a definite internal secretory function, the products of which so far had not been isolated as definite chemical products. There had been isolated a hypothetical substance, to which was given the name of spermin, but that was entirely impure and had no value. In the male the endocrine portion of the testis was situated in the interstitial tissue, and that tissue went by the name of the cells of Leydig. These cells lay between the tubules and showed different degrees of development. In the female the endocrine function was subserved also by interstitial cells and probably further also by the corpora lutea, but certainly before menstruation occurred the corpora lutea action was not present. Now the evidence, experimented and otherwise, proved very defi-

nitely that the internal secretion of the gonads caused the appearance of those signs of body growth which we call secondary sexual characteristics. That term originated with John Hunter. Those secondary changes were the changes that occurred at puberty. There were experiments, especially those of Steinach, which must be mentioned, as they showed the great importance of this internal secretion of the testicles and ovaries. He had attributed so much importance to this interstitial tissue that he had given it the name of the puberty gland—in other words, making puberty entirely dependent upon its action. By experiments on animals he had shown that these secondary sexual characteristics could be produced. Thus male rats which had been castrated before puberty, but in which an ovary had been transplanted, took on secondary female characteristics, and the same was true conversely of rats of the opposite sex. We did not know what the stimulus was that called into activity this property of the gonads. It might depend on the interactivity of other endocrine glands, for instance, of the hypophysis. There might exist gonadal stimulating properties in the endocrine glands. We should find clinical cases in man showing the results of hyper- or hypo-functions of these organs. That is we should find cases of precocious or delayed puberty in both sexes. Then we could study the effects of double ovariotomy. Dr. Quinby reported a case of precocious puberty in a negro child associated with a tumor of the ovary. The child was seven years old, had bleeding from the vagina at the age of four, bleeding recurred with pain in the lower abdomen, the breasts enlarged, there was an abundant growth of hair over the pubes and in the axilla, and there was a tumor in the lower abdomen which was freely movable, but not tender. Family history negative, Wassermann negative, sella turcica normal by *x*-ray. Tumor of right ovary found at operation and removed; left ovary normal; convalescence normal. Unfortunately further history was lacking. A second case was one of hypogenitalism, that is a case of delayed puberty associated with possible hypophyseal dysfunction in a girl sixteen years old. She had never menstruated, was backward in development, but had development of secondary sexual characteristics. She had two symptoms not usually associated with dysfunction on the part of the gonads, those were polydipsia and fainting spells, and suggested disturbance of the hypophysis, but a careful examination failed to discover anything wrong with the cranial nerves or the eye grounds; *x*-ray of the sella turcica showed it to be of a square shape, but not enlarged.

Mild Types of Thyroid Toxic Adenomata.—Dr. MALCOLM S. WOODBURY of Clifton Springs presented this paper. There were two varieties of goiter which were or might be toxic; these were the exophthalmic type and toxic adenomata. The opinion was that adenomata was embryological in origin, derived from fetal rests. Work was being done on this and will be published soon. For the clinician it was important to recognize that adenomata might appear as distinct nodules or there might appear a diffuse process as shown by the microscope, and that meant that the absence of nodules did not rule out this condition. As indicated by recent addresses by Plummer, workers in this field were getting together, old classifications were being altered, the problem was becoming simpler. The recognition of thyroid adenomata as an entity marked an advance. They might attain a large size, but usually not without toxicity. The mild ones might produce only pressure symptoms. The fact that small adenomata might be toxic was true just as it was true of small exophthalmic goiters. Plummer stated that 33 per cent. of all hyperfunctioning thyroids were adenomata. It was obviously of the greatest importance to differentiate toxic states associated with a goiter from psychoses. The term thyrotoxicosis was better than the term hyperthyroidism when applied to adenomata. In a recent short series at Clifton Springs there was a family history in 80 per cent. of the cases; infections of the tonsils or teeth in 90 per cent; and all the patients came from districts in which goiter was rather common. Probably the etiology was somewhat as follows: It appeared that fetal rests might be transmitted more commonly in certain families, or might be due to the water content in localities which required an over-attempt of the thyroid in metabolism adjustment, or to disturbance of the sympatheic nervous system, or to pregnancy. The cells proliferated and took on the form of adenomata. Whether the activity was due to the cells in the adenoma per se or to the surrounding cells was not yet established. Nervous symptoms in the adenomata cases were not different from those in the exophthalmic cases. In adenomata cases 50 per cent. of the patients complained of depression which differed from the depression of psychoses by the absence of self-accusatory delusions. Definite nodules could be felt in half the cases, although palpatation must be done carefully to detect them.

Examinations of the metabolism rate had received a great deal of attention since the portable apparatus of Benedict had come into use, but too much reliance should not be placed in it and it was necessary to allow for differences in weight, age, and sex. An increase of not more than 15 per cent. was to be considered normal. Adenomatous cases might show only a slight increase in basal metabolism or no increase at all; and the question arose whether these were cases in which a toxic element was playing a part. Dr. Woodoury thought they were. The Goetsch test was positive. The patients were operated on by Dr. C. W. Webb, with good results, where the gland was available for operation. The Goetsch test has distinct value in the diagnosis. One point to be emphasized was that solutions of adrenalin chloride varied a great deal according to the age of the solution. This ought to be taken into consideration. Folin had described a test for determining the purity of adrenalin. Dr. Woodbury did not regard the Goetsch test as positive unless there was a rise of over ten points in blood pressure, together with subjective symptoms including tremor. In concluding, he said one was hardly justified in ruling out all thought of a thyrotoxic state because the basal metabolism according to our present methods ran within normal limits. It seemed that cases occurred in which there was no definite rise.

Dr WALTER TIMME of New York said that he would begin his discussion by going back to the time of the Aryan migration into India. Even at that early period there were definite instructions given to the males regarding the females they should choose, with the idea to insure longevity and to produce a race able to survive. Those documents had come down to us today. It was surprising that the subject should have been so long in abeyance and that we were accused of presenting something at this day that was called iconoclastic. Dr. Draper had pointed the way to an advance in the study of immunology. To cite an instance where external characteristics influenced immunity, we knew that in pellagra the infection or the disease attacked in a large majority of cases women, and that the women attacked are either pregnant or in the menopause, and the few cases of pellagra which had sifted through to the north because of the nervous element involved had been diagnosed as menopause psychoses. Now, on the bases of the concomitance of those symptoms those patients could be helped and in some cases cured. It was important to recognize the juxtaposition of those two conditions. Then also in the psychopathic institutions we saw cases that were quite normal in appearance up to the week of their menstruation and then they became maniacal and in that particular week the corpora lutea were in abeyance. We knew that the corpora lutea depressed the activity of the thyroid. Remove that inhibition and one got an excess thyroid activity. If that was recognized at that time and treated at that time, the conduct could be markedly improved, but not in the case of a psychosis. Regarding some of the statements of Dr. Woodbury, the speaker was indebted to him for his paper on the interpretation of the thyroid lobes; it offered some plan for the measure of the standardization of the size of the thyroid. When Dr. Woodbury stated that he would rather use the term thyrotoxicosis there was liable to be confusion. A thyroid might become overactive to overcome the effects of a toxemia, an abscess of a tooth might be the activating factor of an excess activity of the thyroid. It was necessary to differentiate that type of overactivity from the ordinary toxic thyroid. Dr. Quinby's paper brought us to some of the interesting facts that we saw about us without really recognizing the reasons

therefor. He mentioned experiments in transplanting interstitial cells of the male into the female with resulting deterioration of the female generative organs. As a matter of fact, when we had twins born, one being a boy and the other a girl, usually the ovarian secretion of the girl was determined or produced before that of the boy and as a result the boy in twins, the other being a girl, was more retarded both in systemic and mental development. The interrelation of the gonads with the other endocrine organs was of the utmost importance, as shown by the case in a woman of a tumor involving the cortex which produced secondary sex characteristics and cessation of the menstrual function, in which the ovary was not known to have been disturbed. The reason for that was thas both the interstitial cortex cells and the ovarian cells came from the same interstitial tissue, and had effects in common, one of which was on the medulla of the adrenal gland one of the functions of which was to produce hypertension; yet it could be modified by the suprarenal cortex secretion to underact and hence by this means to lower the blood pressure. We could also diminish blood pressure under those conditions by the administration of lutein; we did this in the menopause when we had heightened blood pressure. Now the reason for that was probably that the effect of the corpora lutea was inhibitive of thyroid activity.

Dr. Emil Goetsch of Brooklyn said that we were indebted to Dr. Draper for bringing out a new point of view in the consideration of some of the factors which were related to the ductless glands. As had been shown, we were what our ductless glands were. There was no doubt about that fact. The transition between the normal types and the types that could be considered pathological was a gradual one and was so great that one had difficulty in saying when the normal became abnormal. That was true of functional states also. We could not say when a ductless gland became an abnormal ductless gland. With regard to the thyroid, he thought we had a means of telling when the thyroid was normally active and pathologically active. To determine this we must have a definite test. Unfortunately we had not available tests for all the glands but we had for some of them. After five years of experience with the adrenalin test we now had a means of telling how active a patient's thyroid was. He did think that all cases of hyperthyroidism were abnormally sensitive to the action of adrenalin when administered hypodermically. The negative also held that if a patient did not react he had not hyperthyroidism. Dr. Peabody, working on a large series of soldiers, had confirmed that statement.

Dr. Stockard said that his interest was from the point of view of the embryologist, but he was shocked by the character of the subjects under discussion. Niney-five per cent. of our story was finished when we were born, and up to that time as far as we knew none of the internal secretions had played any part. There was no question but that the structure of a man or any animal was due to the rate at which he developed, and this might be shown experimentally by slowing the rate at any time. It was very easy to decrease the rate in an embryo, and by modifying the rate at different times with relation to gastrilation one could produce all sorts of abnormalities or monsters. We ought not to go so far as to say that the male twin was modified by the female. In the case where there was a mixed twinning in cattle the female was sterile; there we knew that the circulation between the two placentas had an anastomosis which made the blood run through the two, and then the testicle developed before the ovary. When one saw that all the plants and the invertebrates had grown without glands of internal secretion, then one held back when he wanted to regard everything as being due to the disturbance of glands of internal secretion. His way of expressing it was this: We were born irrespective of glands of internal secretion. We might be modified by the maternal glands but our own glands of internal secretion had not done much to us before we were born. Now that little distance we had gone without glands of internal secretion has just as much bearing on how we were going to look later on, because the real shape of our nervous system was determined before that and was independent of our glands of internal secretion. But after we were born then he would admit with everybody that all the future record of growth was dependent on the interaction of glands of internal secretion. This symposium was stimulating and suggestive of possibilities in the future, but at the same time, he thought we would do better and land safer if we realized that there was a long beginning and that was the time to learn because that was the time that rendered itself to study of internal analysis. We were trying to tap the secrets of nature, and he thought we could get something from the structural side. Up to the age of ten it was the thyroid gland that determined what the future structure of the individual would be.

Dr. Samuel W. Bandler of New York said that Professor Stockard was wrong on many points. He had picked out the thyroid gland alone but it was all the glands that acted together and acted before we were born or we would not look like our fathers or mothers. The thyroid acted while in utero, as proved by a case of tetany at birth. When one retarded or accelerated the rate of growth one was doing it through the endocrines. We were what our glands made us, we did what our glands made us do, and think what our glands made us think. Every emotion had an endocrine basis. Man was a composition of anterior pituitary, adrenal cortex, thyroid, and gonad. There was a balance between the glands of the body and between the different glands.

Anterior pituitary	Glandular thyroid
Interstitial thyroid	Adrenal medulla
Adrenal cortex	Glandular ovary
Interstitial gonad	Corpus luteum
Posterior pituitary	Placenta

Every gland was a sex gland, every gland had to do with the sex gland, and also with the development of the muscles and the brain. In the case of cretins one might be due to one gland or to a combination; we could not cure them all with thyroid, we must find what the matter was, one must give what the patient had not and antagonize what the patient had too much of. In regard to Dr. Quinby's cases he ventured to say that the pituitary controlled the flow of cerebrospinal fluid. In his other case the tumor was not the cause of the precocious puberty but was the result. All gland diseases were pluriglandular, it depended on where the cause began to act; it might start in the pituitary but secondarily would affect the gonad. The endocrines presided over the body form and over visceral function and over the psyche. If they did all three to everybody, it would be easy to make the diagnosis, but they did not, and just as one individual when he had syphilis of the testicle or of the bones did not get it in the nervous system, so the average individual with psychosis had a few of the marked distinguishing features. In conclusion he made this prophecy that five years from to-day there would not be one patient admitted to an insane asylum where to-day there are twenty, and endocrines would work the change, and one of the important endocrines that would do it was the placental endocrine with which he had been experimenting for two and a half years, and if he had the time and the voice he would prove that what he said was true.

Dr. George Draper of New York said that he would like to state that neither the humor of Dr. Stockard nor the oratory of Dr. Bandler would prove this point. The problem was not a question of endocrinology, it was the relation of the individual to disease. Now the two subjects had been confused. Studies of the endocrine glands must go on. The clinician was faced with the problem to-day as always of determining the reaction of the individual to disease conditions. We could not analyze cases endocrinologically to determine their susceptibility, and it was for this reason that he found it necessary to devise some written scheme to work out the relationship of the individual to infectious diseases. Bacteriology took up only part way.

Dr. Woodbury said that he agreed with the statements that it was desirable to clean up all sources of infection in thyroid cases whether they were to be treated medically or surgically. Incidentally the metabolism test and the Goetsch test were useful in order to determine the degree with which they were dealing.

THE GYNECOLOGICAL PATIENT OF THE GENERAL PRACTITIONER.*

BY LEROY BROUN, M.D.,

NEW YORK.

ATTENDING SURGEON TO THE WOMAN'S HOSPITAL.

I HAVE thought it might be of mutual interest to present before you this evening some of the symptoms complained of by patients consulting us either as general physicians or as specialists. Practically all of these symptoms and their possible indications are familiar to all of us; it appears to me, however, it will not be amiss for the purpose of a general discussion, to review some of the more prominent ones under a few general headings, and for that reason I bring to your attention *bladder* symptoms, *uterine, abdominal,* and *rectal.*

Bladder Symptoms.—It is not uncommon for us either as practitioners in the general field or as one of those devoting themselves to special lines to have patients seeking relief from frequent and painful urination. This may mean a simple digestive disturbance; it may also mean an infection of a greater or less degree; it may further mean a pathological condition in or about the bladder itself, and lastly it may have as its cause some form of kidney disturbance.

It is readily seen that in order to get at some basis on which to form an opinion it is primarily necessary that we must know the character of the bacterial flora of the urethra for the purpose of excluding gonococci; and, secondly, that we should have a sterile specimen of urine from which not only a culture can be made but also a complete chemical and microscopical examination.

The habit of taking a smear from the urethra frequently yields conclusive results in a negative or positive way. The absence of gonococci enables us to dismiss from our minds the possibility of a certain character of infection.

A sterile specimen is most important and the manner of obtaining it, while thoroughly simple, yet carries with it a few essential points to be remembered. Much can be learned from the examination of such a specimen. My custom is to have on hand a few new bottles with new corks. The bottle is boiled just before using and also the cork, care being taken to stick in the large end of this last some metal instrument that will keep it submerged. After boiling, the bottle is emptied of its watery contents and the cork is pushed into its neck, only the large end being touched with the fingers. In this simple manner we have a thoroughly sterile receptacle for the urine. The urethra having been sterilized with some weak antiseptic solution, a sterile catheter is introduced and the first few ounces of urine that flow through the catheter are not collected. This is for the purpose of getting rid of a part of the clear urine and also that of washing out of the interior of the catheter any remote possible contamination. The remainder of the urine is collected in the sterile receptacle, the last flow being included. The saving of the last residue is important, since by this means we are sure to get all of the sediment which gravitates toward the trigone and from which we can get valuable information.

A sterile specimen having been obtained in the cooled sterile receptacle, it should be sent to a good laboratory, where both a culture and also a chemical and microscopical examination should be made. The information to be gotten from this specimen frequently clears up the condition. Primarily we may find a sterile urine with an abundance of oxalate of lime crystals and a high acidity, indicative of an ordinary digestive disturbance, to be corrected by diet and the use of diluents and belladonna as an antispasmodic. The microscopical report may show abundance of pus, and the culture of colon bacillus alone or colon and staphylococcus. Information of this character would lead us to differentiate between the location of the focus.

A cystoscopic examination of the bladder will readily prove or disprove the presence of a calculus. If present the condition is one for surgery. With its absence the condition may be one of simple cystitis of colon origin, which can be treated by diluents together with urinary antiseptics and a proper diet. In the presence of colon bacilli in the urine the question of colon pyelitis or a colon infection of the kidneys also presents itself. These conditions are usually attended by fever and are recognized by tenderness on pressure in the back over the site of the kidney about the angle of the twelfth rib.

The possibility of tuberculosis also presents itself. Tubercular cystitis with its attending ulcers are uniformly an indication of tuberculosis higher up, usually in one kidney. Urological examination becomes necessary to determine this focus through the catheterization of the ureters and the subsequent examination of the urine from each kidney, together with *x*-ray and thorium examination of the pelvic calices of the kidneys. From the pathological and microscopical standpoint it is not infrequent that tuberculosis though present in the urine

*Read before the West End Medical Society, January 24, 1920.

as drawn from the kidney and detected, is not found in the urine as taken from the bladder. If unfortunately the patient has a tubercular kidney, the condition is one that is surgical, and it has been found that the removal of the diseased kidney quickly results in the cure of the tubercular cystitis.

Our patients in addition to complaining of painful micturition may also add to our troubles by stating that there is blood in the urine. This is readily recognized by the eye in the sterile specimen drawn off, when the blood is in sufficient quantity, or by the microscope of the examiner at a later time. To determine the origin of the blood a cystoscopic examination is again necessary. It may reveal a papilloma of the bladder or malignant disease. If there is no local indication in the bladder itself as an explanation of the source of the blood, the urologist must again be called in for the purpose of determining the condition of both kidneys. As a result of this examination many of the diseases of the kidneys can be recognized, such as renal calculus, colon infection of an acute type, or some new growth or degeneration of the kidney as a hypernephroma or one of polycystic character.

Malaria is also spoken of as giving rise to hematuria. It is rare that we have such conditions, however, in our climate.

As an instance of colon infection giving rise to hematuria, I cite the following instance of a patient who came under my care a year ago: She was a woman of slightly over 50 years and had been having bloody urine for several months with much weakness and debility. Her physician had given her the impression that she had Bright's disease. Complete examination with the collaboration of Dr. Bugbee, the urologist of our hospital, showed that the condition was one of colon infection. With care and diet, urinary antiseptics, and an abundance of fluids the patient was entirely relieved of all symptoms and restored to her usual good health.

Atypical Hemorrhage of Uterine Origin.—The internist seeks always to exclude the possibility of tuberculosis in his examinations. This is the usual primary step. This condition having been excluded he has a clear field for the determination of the pathological condition of which the patient complains. In bleeding of a character other than that of a distinctly normal type our first thought is the possibility of commencing carcinoma.

All conditions must have a beginning and in this state it is unquestionably local in character; later the general system becomes involved and we have a systemic infection. So it is with commencing cancer: in its commencement and earliest stages the condition is distinctly local, free from metastasis, and can be cured by surgical means. The importance of this early recognition must impress itself upon all of us, since we are too familiar with the long and final road traveled by cancerous patients.

Cancer, while a disease of middle life, is, however, known to occur in the early thirties or before; the majority are in and around the period in which we expect the menopause. Uterine bleeding that makes any departure from a normal condition and for which the patient may consult us should be at once thoroughly and carefully investigated by the consultant.

In the modern-day teaching patients are themselves becoming educated as to the possible significance of menstrual disturbances. It therefore becomes imperative that we, as physicians, treat such conditions with due respect and at once eliminate the possibility of commencing cancer.

Fortunately the condition in the majority of instances is easily recognized as suspicious when the involvement is in the cervix. A small wedge section for the purpose of pathological examination from the suspicious area can be taken in the office under procain.

If the cervix is normal in appearance without any erosion, the interior of the uterus should be explored with a small curette. While this can be done in the office, it is, however, preferable both to the patient and also to the doctor to have it done under an anesthetic. From the curettings the pathologist can determine the condition of the lining membrane of the uterus.

The symptom of bleeding in early cancer is due to the rupture and breaking down of capillaries, which are extremely abundant in the involved area. This occurs very early in a large percentage of cases. Unfortunately, however, there is a certain class of endothelial cervical carcinoma, which we call the endogenous type, in which metastasis is early even before any sign of hemorrhage is present. The recurrence in such cases is generally very rapid after operation.

A bloody discharge commencing after the establishment of the menopause is to all of us indicative of the grave possibility of commencing carcinoma of the body of the uterus or of the cervix.

Beginning carcinoma, however, gives at times the first indication of its presence in a profuse flow at the regular menstrual period, amounting at times to a hemorrhage. This may cease and a similar occurrence may take place at the next menstrual time without any bleeding between. This is not unusual, and if not recognized in this early stage, the flow will settle down to a continued show between periods.

The possibility of carcinoma having been eliminated, one may be at ease in determining the source of the bleeding. Not infrequently a cervical polyp or polypoid condition of the endometrium is found; we are familiar also with the bleeding associated with fibroids that encroach upon the uterine canal.

There is a class of bleeding which sometimes, though not always, follows the absence of the normal menstruation for a short time, and which comes from the thickened decidua resulting from a pregnancy outside of the uterus. The classical signs of extrauterine pregnancy are familiar to all of us, as are also those of retained secundines as a result of miscarriage. We must be on our guard, however, against mistaking the profuse flow and discharge of a portion of the thickened decidua (which is sometimes associated with extrauterine pregnancy) for an ordinary miscarriage.

Dr. Farrar, in studying 309 cases of ectopic gestation at the Woman's Hospital, in a very exhaustive article has drawn some valuable conclusions. These are:

1. Pain in ectopic gestation is a symptom that may occur without the preceding bleeding. This

pain is present in every case of tubal pregnancy unless the condition is very early and unruptured.

2. The pain is usually of a cramp-like or bearing-down character, not necessarily of a tearing lancinating kind.

3. Usually one-sided pelvic pain, when associated with peritoneal irritation and collapse, warrants the diagnosis of ectopic gestation though in the absence of the preceding symptoms of severe pain and hemorrhage.

4. The onset of symptoms or an acute attack occurs equally as often at the time of an expected period or just after a normal period, as it does when a period is overdue.

Abdominal Tumors of Pelvic Origin.—A patient coming to us for an abdominal tumor which has existed for a longer or shorter time, must be given some definite information on the condition. The longer we operate the more convinced we are that there are certain conditions of a myomatous tumor of the uterus which make the differentiation between a tumor of uterine origin and one of ovarian origin very uncertain. Such conditions are a globular edematous (soft) myoma of the uterus on the one hand and a tense ovarian cyst on the other. In such instances I think it better to use the term tumor; this will cover both conditions and will be thoroughly satisfactory to the patient.

Myomatous tumors as a rule, however, are not difficult to diagnose; the irregularity and the hardness to the feel make the diagnosis usually clear. The fact that a patient has a myomatous tumor does not stop here. It is highly probable that other conditions exist associated with this tumor. This is not surprising when we recognize that a new growth is going on in the pelvis. There is a marked increased supply of blood, often at times giving venous radicles of the size of a pencil. If there is any abnormal condition present with the adnexa, or present in the endometrium, the increased blood supply is simply adding oil to a smouldering flame and new processes quickly spring up to be associated with the myomatous tumor, which from its size dominates and overshadows the development of the coincident new conditions.

The coincident pathological developments during the growth of uterine myomata are strikingly shown in a study of cases in the Woman's Hospital for a period of ten years. During this time 1,500 patients with myomatous tumors were operated on at the hospital. Associated with these tumors in the above number of cases were 66 instances of malignancy. These included chiefly carcinoma of the body and of the cervix, also a few cases of sarcoma, also a few of carcinoma of the ovaries and also papillomatous ovarian cysts. In these the greater number was carcinoma of the body of the uterus, where there were 20 cases, also 17 cases of papillomatous ovarian cysts. In neither instance would malignancy be recognized as associated with the myoma. In the instances of carcinoma of the body, the hemorrhage indicative of the carcinoma would be attributed to the myomatous tumor. Papilloma of the ovary, while more frequently superimposed on large ovarian cysts, may be and is present in cysts of only a few cubic centimeters capacity. Of the associated ovarian pathological conditions, there were 58 cases, which did not include those mentioned above of papillomatous character.

The fallopian tubes appear to take on a greater number of changes than the other organs, since we find 265 cases of this character, all of which would require an operation *per se*. These changes included such conditions as tuberculosis, pyosalpinx, hydrosalpinx, and salpingitis. Of this number the salpingitis cases, 153 in number, were much more common and evidently directly due to the increased and disturbed circulation of the pelvic organs.

The changes within the myomatous tumor itself were large, being 105 cases. These changes are such as we must expect in any tumor in which the circulation is largely increased and also disturbed in its normal character. There were 83 instances in which the tumor had undergone necrotic changes, also 22 had undergone calcareous degeneration.

It is rather remarkable that we find the appendix also sympathizing considerably in these cases of disturbed circulation. There were found 167 cases of diseased appendix, either of the subacute or chronic character, all of which required separate operations.

Subsequent study of a year's work of 262 consecutive cases of myoma bring out practically the same results, in which it shows that there are over 5 per cent. of these tumors undergoing necrotic changes.

Fibroids under certain conditions do not give any symptoms. In such cases the physician may at times discover the presence of the fibroid sufficiently large even to extend outside of the pelvis and yet the patient is not aware of it. Such fibroids do not require treatment or operative interference.

The development of coincident pathological conditions in either the adnexa or the fibroid itself, or the development of adhesions, all give rise to pain of a greater or less extent. It is for such a symptom as pain that a patient will present herself to the physician and the discovery of the fibroid is made.

Again a fibroid developing within the muscle of the uterus or on the peritoneal side, does not give rise to hemorrhage. It is not infrequent to elicit the history of only a three or four days' menstrual flow with fibroids of large size. When the fibroid develops towards the lining of the membrane of the uterine cavity, certain changes are brought about in the endometrium and we have as a result hemorrhage of greater or less severity. It is for these two symptoms, *pain* and *hemorrhage*, that a patient may consult her physician. As spoken of before, the hemorrhage may have as its possible cause the commencement of a malignant disease of the endometrium or the development of the fibroma towards the uterine cavity. Taking this rational view of the pathological condition present and of its associated complicating conditions, it is readily seen that any of these associated pathological conditions occurring with the fibroid contraindicate any other form of treatment of the tumor than that of surgery.

The changes in the myoma itself such as necrosis, calcareous degeneration, also those including the tubercular changes of the endometrium, ex-

ist in 7 per cent. of myomata. Tubal conditions exist in 7 per cent., as also malignant diseases of the body of the uterus. All of these would contraindicate the use of radium or *x*-ray and can be properly treated only by surgical measures.

Fibroids that can be well mapped out and are shown to be free from adhesions and from any complications outside pathological conditions, and which result in hemorrhage for which the patient is seeking relief, can very well and wisely be treated by radium and the *x*-ray, carcinoma of the body of the uterus having been excluded by a previous curettage. It is in such a class of cases that I think radium and the *x*-ray are of value, in that we can save the patient from operative measures.

Fibroids that have been accidentally discovered by the physician, which have given rise to no pain or hemorrhage, and of the presence of which the patient was not aware until the physician discovered it, I do not think require treatment of any character. It is only necessary in such conditions to reassure the patient and have her enthusiastic support in an examination at regular intervals.

The statement that fibroids undergo sarcomatous changes to the extent of 2 per cent. has been handed down in various text-books. I doubt the accuracy of such a statement. In our series of over 1,700 cases, less than four-tenths of 1 per cent. were found sarcomatous. In 8,988 cases collected by Lewis and Olshausen, only 1.3 per cent. were sarcomatous and von Gurltz reports that out of 883 cases only two of sarcoma were found.

Ovarian Cysts.—This class of pathological conditions should always go under a surgical operation, for the reason that experience has taught us that a certain percentage undergo malignant changes, ordinarily of a papillomatous character. While it is more likely that this degenerative change may have taken place in the cyst wall of the larger cysts, it is, however, not uncommon to find the condition in very small cystomata, even those of but a few cubic centimeters capacity.

There is a class of cysts, however, that appear to take care of themselves. I refer to those of corpus luteum origin. These form and frequently after an interval of a month or two disappear even though they may have been of the size of 500 c.c. capacity. They are thin-walled unilocular cysts of a serous type.

There is hardly any one of us who has not had the experience of discovering such a cyst and within a short time, a few weeks or a month, find the cyst no longer exists. The escape of the serous contents into the peritoneal cavity has given rise to no trouble. We have all had the experience of discovering such cysts and of having them examined by a second man for the mental comfort of the patient and getting a statement that no cyst was found. This is mortifying, but the knowledge of the history of such conditions relieves the examiner and spares the consultation.

Rectal Examinations.—Bleeding hemorrhoids complained of by the patient should never go without a thorough examination, which should include a proctoscopic examination through a proctoscope with a light carrier. The only chance that the patient can have for the cure of rectal cancer is an early recognition. Medical history is full of just such oversights made by the busy practitioner. The appliances necessary are simple, an ordinary proctoscope and a light carrier. The patient after having had the bowels previously emptied is placed in a knee-chest position, with all stays or any confining bands around the abdomen removed. The rectum itself will balloon up as soon as air is permitted to enter on the placing of the proctoscope. The wide and satisfactory view that can be obtained by the examiner with the aid of the light carrier is most gratifying. Malignant diseases higher up beyond the reach of the view given by the proctoscope must be determined by the *x*-ray examination and shadow-producing enemas and meals.

This rambling review of some of the cases that present themselves to us, I hope, may elicit sufficient interest to produce a discussion. The examinations used by the specialist and his method of procedure to fix the site of the trouble in the greater majority of instances requires only a few ordinary appliances and no special skill in handling. The bladder and rectal examinations can easily be made by placing the patient in the knee-chest position for both examinations. For the bladder examination all that is needed is a Kelly's direct-vision urethroscope. For the rectal examination a simple proctoscope. The same light carrier can be utilized in both. For the cystoscopic examination it may be necessary to dilate slightly the urethral entrance; for that purpose a cone-shaped dilator and a 10 per cent. procain solution are needed. Concerning the knee-chest position a few details are necessary for the best results. The knees should be vertical and not slanting under the body. The patient should rest on her chest and bosom. The corset should be removed and all constricting bands about the abdomen should be loosened.

148 West Seventy-seventh Street.

THE BALANCE BETWEEN THE ENDOCRINES AND IN EACH INDIVIDUAL ENDOCRINE.

By SAMUEL WYLLIS BANDLER, M.D.,

NEW YORK.

PROFESSOR OF GYNECOLOGY, N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The cerebrum is affected by stimuli through the senses (sight, hearing, smell, taste, touch, pain and temperature, etc. The automatic nervous system has its intimate and close relation with the cerebrum. Stimuli through any of these senses cause reaction, instinctive action, unconscious and conscious action. Volition, thought, etc., are functions of the psyche and the mind. As a result of certain stimuli, particularly and definitely such as are associated with the instincts and playing their part in arousing emotions, there is response on the part of the autonomic nervous system, on the part of the visceral organs and structures with which they are connected, and a response on the part of the associated endocrines. The autonomic nervous system, in its relation to the endocrines, is responsible for and responds to the instincts and emotions. The autonomic nervous system may be divided broadly into the vagus and the sympathetic which produce opposite or opposing actions in the structures, organs,

and endocrine glands which both innervate and supply. A relation between the two divisions of the autonomic system exists and is supposed to preserve that equilibrium and normal balance essential to normal action and normal response in the functions of the organs which they supply. An excessive control above the normal balance on the part of one or the other, or variations in their normal balance differing from the normal, are productive of abnormal action. In many conditions the blame may be laid on overactivity or underactivity of one or other of these branches of the autonomic nervous system and hence in the same disease there are minor variations from the typical or supposedly pathognomonic signs.

A study of the innervations and resulting normal functions regulated by the autonomic nervous system and the diagnosis of altered or abnormal function of any of the structures so innervated constitutes a very difficult problem and from the standpoint of therapy leads us nowhere, since the real cause is thereby neither divulged nor attacked. Our real field lies in studying the endocrines themselves.

The endocrines likewise respond to impulses sent to them through the autonomic nervous system, and the endocrines respond according to the strength of the impulse, but more particularly according to their own development, capacity, vigor, and the balance existing between the component parts of each endocrine gland. The endocrines may be underactive, normal, or overactive. They may increase or diminish in power and in secretory activity in varying degrees through the different periods of life, in the performance of physiological functions, and during disease and infections.

The important point first to be held in mind is the normal, stable balance or interrelation between the various endocrines of the body. Of equally great importance is the preservation of balance between the various hormones produced by any one gland. In the pituitary the two most prominent secreting areas are the anterior lobe and the posterior lobe. In the adrenals we have the cortex and medulla totally different in structure and character, as well as in the influence and the action of their respective secretions. In the ovary, we have the interstitial or interglandular structure and the follicular part of this gland. When ovulation takes place in association with menstruation, and probably long before this, we have the false corpus luteum. When pregnancy takes place we have the true corpus luteum. It is the corpus luteum which is responsible for hyperthyroidism. In the thyroid we certainly have two different secretions, one from the interstitial portion and a different one from the glandular, and this accounts for the various types of hyperthyroidism and of Basedow's disease aside from the fact that the severe forms of hyperthyroidism are pluriglandular upsets. In the pituitary there is a certain normal balance of relation between the anterior and posterior lobes. In the adrenals there exists what may be determined to be or be called a normal balance between the cortex and the medulla and the same is to be said of the interstitial and glandular portions of the ovary. It must be stated here that the ovary functionates long before menstruation is established, probably from the earliest years, just as do the other endocrines, and that a so-called menstrual wave in the vast number of cases is not looked for, noticed, or observed. It is, as a rule, not evidenced by any type of reaction. But in many cases, if looked for, there will be noted regular monthly evidences of this internal process and in these cases it is productive of the same type of premenstrual nerve and psychic phenomena as is recognized in older girls before each monthly outpouring of blood from the uterus. Only when the corpus luteum enters into the field do hyperthyroidism and Basedows disease appear as a rule.

Any endocrine composed of two recognized and distinct parts may overact in both or underact in both. Overactivity may involve one part and the other may functionate normally. One part may overact and the other underact. The important point is that to whatever degree one part overacts to the same degree may it *overtop and inhibit* the action of the other, and this difference may not be made visible by corresponding anatomical differances in size in the respective parts of the glands. Overactivity of the anterior pituitary often diminishes the secretory activity and action of the posterior, though in the early stages the posterior may have been likewise correspondingly active; and this is well exemplified in acromegaly with its early glycosuria.

Overactivity of the interstitial ovary may be associated with varying degrees of inhibition of function of the glandular part. The reverse also holds true. But persistent corpora lutea inhibit ovulation, inhibit the normal action of ovarian secretion and rouse the thyroid. Overactivity of the adrenal medulla is generally associated with underactivity of the cortex. And here as in all glandular organs we have what might be called two secretions antagonistic to each other.

What a vast meaning does this bear to the question of therapy. Taking these factors into consideration, we see how the balance in any one gland may be disturbed and how we may have numerous combinations of over and underactivity in the interrelation between the various endocrines as well as in their respective component parts.

If we study the action of the endocrines and their respective hormones and recognize the specific action of the hormone on the body in general and on definite and specific areas and functions of the body, there is no need for introducing into the diagnostic or therapeutic sphere any complicated or complicating interest in the autonomic nervous system. We may be able from the standpoint of therapy by giving gland extract, to supply what is lacking, or to inhibit excessive function of any gland or part of a gland, eventually arriving at rational or exact therapy. However much the endocrines have to do with external form or characteristics, with physical, visceral, and metabolic functions, they have as important and specific relations to the nervous system, to the mind, to the instincts, to the emotions, and to the psyche. And since every gland and its component parts is concerned with each of these spheres, it is well to remember that over or underactivity of any endocrine gland may be limited to or manifested particularly in one, two, three, or more of these

spheres of activity. This explains the neuroses and the psychoses. Hence the value of ovarian extract, (whole gland) and of ovarian residue in the treatment of peristent corpora lutea and of hyperthyroidism and Basedow's disease.

Among its other functions the nervous system is concerned with activities of a motor and trophic character. To illustrate. If the cells of the anterior horn are affected by toxins, as in acute anterior poliomyelitis, the nutrition of the muscles which they control and govern is affected. We do not know whether the normal nutritional control or domination exercised by these cells is effected solely by impulses of an unknown character sent out to these muscles from the anterior horn cells, or whether the protoplasm of these cells really produces substances analogous to enzymes which reach the muscle fibres along the motor path and so exert a direct nutritional or chemical influence on the muscle fibre. Probably both forms of energy are operative.

There seems to be a parallelism or resemblance between this action of the anterior horn cells and the all important action of the endocrine organs. These endocrines exercise their influence in two ways: One directly through the autonomic system, of the nature of an impulse stimulus to specific areas of the organism (for instance, pylorus, intestines, uterus, muscles, etc.) again, and this is the all important point, the endocrine substance themselves pass out through the blood and lymph channels directly to these cells, muscle bundles, structures, and nerve ends with whose functions of growth and continuity of function they are specifically concerned.

When an emotion is aroused, the immediate impulse from the central nervous system, be it from the higher cortical centres or those of less pretentious control (those of the medulla oblongata, for example), exerts its initial influence on the endocrine along the autonomic system, and also on the cerebrospinal axis. The latter is required for voluntary and for reflex motor activity acting on the motor system. On the other hand, the visceral structures receive their specific impulses through the autonomic nervous system (vasomotor, sphincteric, in embarrassments, frights, etc.). The latter system likewise carries impulses to the specifically associated endocrine. The outpourings from the latter (endocrines), as they are adaptively stimulated by the various emotions, immediately reinforce and continue the specific type of activity instantaneously called forth by the original impulse. On the degrees of outpouring and on the variety of glands so stimulated depends the behavior of the individual concerned.

If an emotion, resulting in the outpouring of the adrenal secretions, includes adrenalin only, without an associated adequate response by the cortex of the adrenal, and of other glands, the emotion is one of fear or terror. If with the outpouring of adrenalin there is an adequate outpouring from the adrenal cortex, the emotion tends more to that of anger. If with this adrenalin outpouring there is joined an adequate response by the posterior pituitary, as is the case when the maternal instinct or the sex instinct is roused, it enhances the action of the adrenal medulla or the cortex or both. If the anterior pituitary responds to an emotion, there is the added element of strength, as is likewise the case with the adrenal cortex, but what is more important, the presence of anterior pituitary outpouring adds the elements of judgment and self-possession.

When an emotion is aroused there is a certain action of the autonomic nervous system plus a certain action of the motor apparatus and an associated action in one or other of the endocrine structures. These determine by their response the behavior of the individual concerned and in their various combinations are characteristically described as emotions with definite names; and the psychic behavior as well as the physical behavior are recognized so readily that by the facial expression alone we label the various manifestations as anger, fear, terror, joy, sorrow, etc. The way an individual behaves and gives outward expression to his emotions varies according to his instincts and their makeup and to the endocrine structures, their relative strength, and their associated response, to any stimulus.

A person may ordinarily not be courageous but under a stimulus which rouses an instinct and its associated endocrine activity, into a great emotion, he or she may show the greatest courage and heroism. One may be brave and yet use judgment. Hence it is not always a discredit if we say "He who fights and runs away, may live to fight another day." A courageous individual may be reckless or foolhardy. It is easy to understand how the maternal instinct and its associated gland reponses may be so aroused that the outpouring of posterior pituitary secretion would result in a glorious or brave act when perhaps no other stimulus, acting on any other instinct or producing any other emotion could prompt this adequate endocrine reserve of energy, force, or physical power.

I consider the anterior hypophysis to be all-important gland of mental maturity. We know how important it is in association with the thyroid particularly, in aiding and causing proper mental development. But this gland gains in importance in a trophic cerebral sense after the early twenties. The knowledge a person may acquire, the information he may have gained, when put into the melting-pot called experience and amalgamated as it should be into a harmonious, stable combination, may or may not be associated with wisdom, judgment, and philosophy. Some people even at the age of forty or fifty years have the same youthful immaturity of mind as in their younger years. They have gained nothing in mental stability and have profited little if any by experience. Compared with what they might have been and what might be expected of them at this age, they are, so far as wisdom is concerned, hypoplastic or morons of varying degrees. This comparison is not based on any test as to the ordinary functions of the mind, but is concerned with the question of mental maturity. We might well expect the same varying degrees in the ripening of judgment as we find during the earlier years in the ripening of body-development, mental development, sex-development, etc. There may be no improvement as to maturity of mind, there may be delayed development, there may be a precocious or an unusual development.

The thyroid gland is the gland of energy. It speeds up and activates all the functions and organs, even the tongue. Hyperthyoid people talk more, more continuously or quickly. What is said depends upon the instincts, emotions, and the cerebrum which is being urged to talk. With a poorly-stocked cerebrum, the output is of no importance. With a good cerebrum, well-impressed with knowledge, information, a wealth of good ideas, the lingual output is worth while. The mixture and associations of ideas are personal and give us a good index of an individual's tastes, likes, emotions, and endocrine make-up. If such a mind is abnormally stimulated by both thyroid and adrenals and the person is of adrenal mentality, the ideas expressed are along the line prompted by the instincts and the emotions with which the adrenals are concerned; such as, sports, feats of strength, pugnacity, fear, anger, anxiety, suspicion, and possibly certain forms of sex questions.

If the cerebrum, stimulated by thyroid, is actively stimulated by the posterior pituitary, thought and talk may be along lines of the instincts and emotions with which this portion of the pituitary gland is associated, such as feminine matters, romance, children, or along sex lines.

I believe the anterior pituitary to be associated not only or always with strength of body but decidedly with strength of mind. Its normal activities, so far as its trophic connection with the brain is concerned, lead to mental maturity, to judgment, to philosophy, to self-control. Under associated thyroid stimulation, an individual with such an anterior lobe would show wisdom, and in this class fall the wise, the elder statesmen. Since the anterior hypophysis is a gland whose activities are associated, if we might so say, with intellectual instincts and emotions and with the control of the other instincts and emotions, either or both of these activities lend themselves to the development of brain character of the better sort. The anterior pituitary when dominant and in control, may limit the activity or inhibits the activity of the sex glands, the posterior pituitary, the adrenal cortex, and the testis.

Viewing the hypophysis gland from the standpoint of its relation, in a trophic sense, to the genital tract and to sex function, we must take into consideration both the anterior and the posterior lobes. Proper secretory activity on the part of the hypophysis is essential to normal development of the uterus, tubes, and ovaries. The anterior lobe is concerned with growth in general, stimulates the development of the body, bone, muscle, and mind, and therefore includes within the sphere of its activity, the sex organs. During pregnancy the anterior lobe undergoes specific stimulation in its structure and activity, and the resulting changes in the gland are so marked and distinctive that after labor, certain of these structural alterations remain. It can be readily understood that the anterior pituitary, as well as other glands, may therefore bear an important relation, in the way of stimulation, to growth as regards the embryo.

In the early stages of acromegaly, there appears to be an overstimulation in the genital tract followed later by evidences of diminished stimulation, and thereafter regressive changes and atrophy occur in the genital tract. But this early stimulation is part of the general growth associated with acromegaly and is not more specifically related to the sex organs at this time than it is to other areas of the body. In addition, the posterior lobe likewise is overactive at first.

The subsequent regression in the genital tract is due partly to the diminution of posterior lobe activity, since this part of the gland is much more specifically related to trophic support of the genitalia than is the anterior port of the gland. The posterior lobe, from which is obtained pituitrin, has the well-known action during labor since it increases the force of the uterine muscle contractions. It is the gland whose secretion is responsible for the Braxton Hicks' painless contractions of pregnancy, for the normal rhythmic contractions of the non-pregnant uterus which aid in keeping the uterine musculature normal in character and tone; for the excessive contractions during menstruation which, in so many cases, constitute the physical annoyance called dysmenorrhea. When labor is instituted the posterior pituitary evidences its specific contractile functions in heightened form by producing the physiological labor pains during what is really an endocrine crisis, that is, labor. To develop a uterus normally a girl must possess sufficient of the trophic element of the various glands which stimulate body growth in general, and among the most important of these is the anterior pituitary. She must however possess enough of the trophic element which in addition specifically and regularly produces painless uterine automassage or contractions and this is furnished by the posterior lobe of the pituitary. A lack of sufficient secretion from one or the other or a relative insufficiency of both or of either, give us, the varied degrees of infantile uterus, uterine hypoplasia, or delayed development of the uterus.

After normal size and development of the internal genitalia have been attained, insufficient action on the part of the posterior lobe is responsible for atrophy of the uterus. While failure of development may be due to a minus of the anterior lobe in the early years, minus of the posterior is in adult life the much more important factor in causing atrophy. My therapeutic endeavors indicate that the administration of anterior pituitary extract in fibromyomatous tumors of the uterus has an action totally opposed to the stimulating trophic effect which the posterior lobe exerts upon the uterus and on menstrual function. To repeat, while the anterior lobe is important in the early years for the development of the genitalia, it is the posterior lobe which is important, especially later, for preserving the normality of what has been developed, and it is in the posterior pituitary that we possess the important trophic factor which through overactivity is responsible for fibromyomata. It is probable that the anterior lobe increases the connective-tissue elements of the uterus and the posterior lobe is related to the muscular fibres. Fibrosis uteri is a result of frequent and repeated pregnancy and it is known that after each pregnancy there is a tendency to an increase of the connective-tissue bundles. In acromegaly the muscular tissue of the body evidences changes of this type. It is therefore conceivable that myomata are

due to the posterior pituitary overactivity. Fibrosis uteri and pure fibroids may be due partly to anterior lobe activity. Fibromyomata are due to a combined overaction of the two lobes exerted specifically on the uterus, with the rôle of the posterior lobe as the important factor. Hence in pure fibromata (anterior lobe), there should be less tendency to glycosuria than in myomata, since the latter are due to posterior lobe overactivity. I have a history of three sisters with fibromyomata, on two of whom I myself have operated. The three sisters have the same father. One is born of the first wife, the other two of the second. The point of heredity in this, showing the transmissibility of gland instability or of gland dominance, is that the father, a man of small stature, shows from the description which has been given, all the evidences of a physical nature of anterior pituitary lobe minus. He is small and so are the children, has had little hair on the face in the way of beard, has little hands and little feet. A son has "nodules" of the scalp.

The ovary has at least two if not four structures capable of producing a secretion: (1) The follicle apparatus. (2) The stroma or interglandular apparatus including those typical interstitial cells said to parallel the interstitial cells of Leydig in the testis. (3) After ovulation is established we have the ripening and rupturing Graafian follicles and the corpus luteum of menstruation. (4) When pregnancy takes place the corpus luteum which gives out the ovum, continues to develop for several months, through the reaction and stimulation produced by the decidua and especially by the growing ovum. The secretion produced by the growing ovum is a secretory cell off-throw from its outer covering called the trophoblast. From this trophoblast develop the future chorion and placenta.

Now the follicular apparatus of the ovary is influenced by and related to menstruation. The menstrual and premenstrual activity of the ovary calls into play, and is associated with, activity of the posterior pituitary, the adrenals and the thyroid. The relation of follicular function is particularly dependent on normal posterior pituitary stimulation. It is the follicle apparatus which stimulates the adrenal medulla while the interstitial portion of the ovary stimulates the adrenal cortex and the anterior pituitary. The corpus luteum stimulates the glandular thyroid and is supposed to inhibit the posterior pituitary, but it often rouses the post pituitary.

The interstitial ovary is a secretory tissue which acts, probably in association with the immature follicles, long before menstruation is established and this activity is evidenced by the fact that the physical conformation of a girl and the secondary sex characteristics are in evidence before menstruation is established. If we bear in mind the picture of ovary (follicular), adrenal medulla, posterior pituitary, and thyroid (glandular) as the more predominant relation in the girl, and testis, adrenal cortex, and anterior pituitary and thyroid interstitial, as the more predominant in the boy, we can then readily understand the difference in the shape of the pelvis in the two sexes, a difference in the skeletal structures and in the muscles, the difference in the distribution of hair and fat, and the marked differences in taste emotions and inclination. In the male we have in the gonads a different relation or type of secretion, especially when we consider what are known as the interstitial cells of Leydig. To the gonads of the boy, before puberty as well as after, must be attributed a secretory action, since it is already then indicated by the differences called secondary sex characteristics. These differences become very evident and more marked as boy or girl advances towards puberty and on through adolescence. And so in the boy or girl deviations to the female type in the boy or deviations to the male type in the girl have a significance which from the standpoint of therapy should not be underestimated.

Therefore there are only two possible explanations for these marked differences in sex characteristics and in the instincts, emotions, tastes, and play of the two sexes. Either the ovary contributes a secretion directly responsible for these secondary sex characteristics (as mammary glands, etc.) or these characteristics result through modifications produced by the glandular ovary in pituitary, adrenals, thyroid, and other glands, or else both factors, as is probable, enter into consideration with the latter factor of most importance.

The gonads of the boy and man either produce a secretion directly responsible for the secondary sex characteristics, the subsequent distribution and growth of beard, etc., or else these effects are produced likewise by gonadal Leydig stimulation of associated glands. It is probable that both factors hold true, with the latter factor of most importance. The ovaries are giving off their secretion from birth on. Ordinarily the corpus luteum of menstruation should appear at puberty, but it, often enough, develops in earlier years and is so responsible for much that has been overlooked.

Early ripening of the ovaries and the girls early entrance into the menstrual function hasten those changes in the epiphyses which inhibit growth in bone length. This results in shorter stature. This is produced by a stimulation of the posterior lobe of the pituitary and a consequently lesser degree of stimulation or a relative inhibition of the anterior lobe of the pituitary. Tall, thin stature may likewise result from the same form of overstimulation of the adrenal medulla as compared with the cortex. On the development of menstruation, the posterior pituitary and the adrenals enter into still greater play with the glandular part of the thyroid in the processes associated with menstruation. If the posterior pituitary enters early into greater activity than normal, it may to this degree relatively or actually "overtop" the action of the anterior lobe.

Late ripening of female and the male gonads may be associated with tall stature. It is well known that in eunuchs tall stature results after castration. Since the cells of Leydig, etc., no longer stimulate the adrenal cortex and all stimulation of the pituitary is diminished, adrenal medulla growth in stature takes place. The removal of this pituitary stimulation is of the type which causes a loss of balance, in this sense that the posterior pituitary diminishes in activity relatively less than does the anterior lobe. As a result of anatomical studies in eunuchs there is noted an excessive growth and action of

the pituitary and this becomes evident in association with overactivity of the adrenal medulla in changes in the voice, absence of hairiness, tall stature, but not the broad, thick, powerful chest. Primary excessive action of the anterior pituitary instead of stimulating the ovaries inhibits their activity, as I have proven often enough by therapy. So marked is the effect of well-developed acromegaly on the ovaries, since posterior lobe activity is often correspondingly diminished that many have been tempted to consider ovarian insufficiency as the cause of acromegaly rather than the result of the same, and both types of etiology are certainly possible. Just as deficient normal ovarian function may result in increased body-length because of a relative overactivity on the part of the anterior lobe through lack of proper stimulation of the posterior, so the reverse may be true. It must be remembered that this element of growth in body length is considered during the period of adolescence mainly.

With these and many other facts in mind, it is more than suggestive that the two secretions of the ovary and of the testis act not only by virtue of these secretions exerted specifically on certain areas and processes of the body, but that they do so more decisively by varying degrees of stimulation and inhibition of the associated endocrines, and that differences in the balance between the interstitial and glandular part of ovary or of testis are of huge importance.

Man is more hairy because his gonads act directly on hair growth or more probably because the cells of Leydig stimulate the hair-producing function of the adrenal cortex and the anterior pituitary. Woman is less hairy because the interstitial ovarian secretion cannot so stimulate growth of hair on the face, chin, chest, back, and legs. The interstitial gland of the ovary cannot stimulate this function in the adrenals as much as do the specific cells of Leydig. In addition however, the glandular ovary stimulates the adrenal medulla and inhibits activity of the adrenal cortex. The glandular ovary stimulates the posterior pituitary and relatively inhibits the anterior pituitary. The interstitial ovary stimulates the anterior pituitary and adrenal cortex and relatively inhibits posterior lobe activity so that differences in balance, if marked, in the ovary have an influence on body growth. The interstitial ovary stimulates one part of the thyroid, the glandular ovary the other, but the corpus luteum of pregnancy stimulates the glandular thyroid and the adrenal medulla, but normally inhibits the posterior pituitary.

Men vary for these reasons in the hairy growth on the body and face and in the type of its distribution. Women vary in the type of distribution of hair and in many, more especially about the menopause period, when there is a rearrangement of the gland relations, there are varying degrees of hair growth on face and chin. Because of atypical interglandular relation, many women from their earlier years have hair on the arms, thighs, and body of the male type. Therefore, while there may be less hair and beard than usual in many men, there may be more hair than normal on body and face in many women. It is more suggestive to say that in the female, ovarian secretion, by failure to inhibit the specific hair function of the adrenals and the hypophysis, has resulted in hairy growth resembling that noted in men. There is in men more adrenal cortex function and relatively speaking, greater function in the anterior pituitary than in the adrenal medulla and posterior pituitary respectively, though the function of the latter two may be either normal, increased, or deficient. In men, failure to stimulate hairiness points to actual or relative diminution of adrenal cortex function and to actual or relative diminution of the anterior pituitary. With this condition the adrenal medulla or the posterior pituitary activity may be of varying grades.

Now the posterior pituitary, important as is its action in men, is less essential to the sex functions and sex urge in them because of the added effects of the adrenal cortex and the cells of Leydig. The posterior pituitary certainly has a specific action on the uterus during labor. It is partly responsible for the tender emotions in women. Women have smaller hands and feet. They have a typical distribution of the normal fat of the body, they have no beards. Therefore it is rational to conclude that the posterior pituitary, in close association with the ovary, the glandular thyroid, and the adrenal medulla, is responsible not only for the secondary sex characteristics typical of the female, but for her tender emotions and her emotional tendencies. If in a man the posterior pituitary is not overtopped by the anterior, and the adrenal medulla by the cortex, his tender emotions are present.

Since the anterior pituitary, in association with the adrenal cortex is concerned with growth, development of the hands and feet, of bone, of broad, thick chest, and the element of strength, it is suggestive that the male gonads stimulate those glands and make their activities more evident in men than in women. This does not alter the fact that a primary inherited anterior pituitary overactivity or one acquired through intercurrent causes (study, etc.), while associated with growth in stature or growth of mind may not be associated with an adequately good adrenal cortex or gonadal structure.

However much the anterior pituitary, through stimulating general growth, may have to do with development of the uterus, an associated adequate activity of the posterior lobe, is of the greatest nutritional importance to the genitalia. The posterior lobe takes a most specific and active part in menstruation and labor, and is the most important causative factor in dysmenorrhea. It is therefore more than suggestions (and therapy in many cases to be reported verifies this contention), that an overactivity of both anterior and posterior lobes up to a certain age is responsible for a large size of the uterus, for elongated uteri, for elongatio colli. After the developmental stage has been passed, the posterior lobe is the important nutritional factor and its overactivity is the most important element in the production of fibromyomata, whereas fibrosis uteri probably bears a relation to anterior lobe activity also.

In my obstetric experience between ten and twenty per cent. of pregnant women evidence to the tactile sense fibromatous or myomatous nodules in the uterus in the latter months of pregnancy. These are distinctly recognized by the external hand

after the placenta has been expelled and uterine contraction has taken place. Subsequent bimanual examination confierms this diagnosis. It is remarkable how nursing, as it brings the uterus back to its normal involution, usually aids in the total disappearance of these nodules which may be isolated or discrete, single or generally multiple. Since when the mother nurses, they disappear entirely after a few weeks, as a rule, such as disappear are recognized to be myomata rather than fibromata; such as do not disappear are fibromata. The above discussion serves to illustrate the reason for my referring to the anterior hypophysis as more of a male than a female portion of the gland; it does more work in the development of the body, in the production of strength and maturity of mind, and, in association with the adrenal cortex, and cells of Leydig, and the interstitial thyroid is responsible for masculine instincts and emotions.

The reason for calling the posterior lobe more a female gland than a male gland is because of its specific action during menstruation, pregnancy, and labor, and because its other activities, in association with the adrenal medulla, the glandular thyroid and the ovary and the corpus luteum are evidenced in the feminine instincts, emotions, and psyche.

Hence, in whatever respect or degree a woman resembles the male in body form, size, distribution of hair, instincts, emotions, and tastes, to that degree is my attention attracted to the adrenal cortex or the anterior pituitary or both and to the interstitial ovary.

To whatever degree or extent the male resembles the female in shape of pelvis, hands, distribution of hair, lack of beard, tastes, instincts, and emotions, to that degree do I incline to the notion of actual or relative preponderance of the posterior pituitary and the adrenal medulla as compared to the normal balance expected in his sex.

Among the functions of the adrenal medulla (adrenalin) is the preservation of the tonus of the organs innervated by the sympathetic, and of course to that extent these organs and their function are dependent on the adrenal medulla. It maintains the sugar content of the blood. It is concerned with the regulation of blood-pressure and the distribution of the blood. It increases the excitability of the striated muscles; it relaxes the stomach and intestines, and contracts the pyloric and ilcocecal sphincters and the internal sphincter of the anus.

Under conditions tending to induce fear, if the adrenal output is adequate to produce and enhance these normal processes with a certain degree of intensity, and if the cortex, especially if associated with the action of other endocrines, acts in harmony, the individual shows fright of varying degrees, is able to run away and to show judgment. If the added action of the adrenal cortex is of sufficient intensity, the emotion aroused is anger. This is of varying degrees of intensity and is associated with the instinct of pugnacity. If, on the contrary, there is no adequate response by the adrenal medulla, little or none by the adrenal cortex, or the posterlor or anterior pituitary, the emotion of fear becomes that of terror with inability to flee, and total disorganization of physical, mental, and psychic processes. The adrenal cortex is necessary to stabilize the above-mentioned physical and psychic processes produced by action of the adrenal medulla.

Since the thyroid, if normal or overactive, accentuates other functions and emotions, a hyperthyroid person will show to an exaggerated degree any of the emotions dependent on good or faulty endocrine response. The cowardly manifest the physical tendencies to retreat and to flee. In the intense degrees of fright, called terror, there may be even relaxation of the sphincters, a condition which is the reverse of that produced by normal adrenal sufficiency.

The courageous go forward or hold their ground. In the emotion of anger attending the instinct of pugnacity not only does the adrenal medulla functionate actively, but there must be a corresponding activity and stimulation of the cortical portion. In other words, an individual is fearsome in varying degrees primarily according to the degree of adrenal response to stimuli. An individual is courageous and bold because of good adrenal response, both medullary and cortical.

The type of courage depends on the element of judgment and self-control. A person may be courageous but not foolhardy, or he may be reckless or thoughtless. What would ordinarily be fear or terror may be manifested as anger or courage if an associated emotion brings into play another endocrine associated with that other emotion. For instance, the posterior pituitary, which is associated with the maternal instinct, will respond when that instinct and its associated emotion are aroused, and it then reinforces the action of the adrenals, for instance, in a state related to fear. In the manifestations of fear, anxiety, suspicion, etc., related as they are to the adrenal medulla, the associated behavior of the cortex and the other endocrines is important in determining the variations, the degrees of severity, and the direction and duration of these states.

Phobias and anxieties associated, for instance, with abnormal or excessive coitus point to weakness or diminution in activity on the part of the adrenal cortex. Then the character of this abnormal state is influenced and determined by the character and interrelation of the anterior pituitary, posterior pituitary, thyroid, etc. The greater is the associated activity of the anterior pituitary, the greater are the judgment and element of control in these states of anxiety. The action of the anterior pituitary in states of anger and under conditions requiring courage assists in directing the course of action. Of course, we must include the previous influence of the anterior pituitary on the cerebrum, etc., as well as its response in an emergency.

The endocrines are therefore closely related to sleep, the production of sleep, to sleeplessness, to the dreamy waking state, and to dreams. The endocrines stimulate, arouse, and recall in the lower and partly in the upper consciousness emotional memory pictures. Whatever action the original event, occurrence, or picture roused in them in the way of response to an emotion, their activity and action during sleep brings back the same or a symbolic picture in the brain.

Now the brain, while it may be likened to a cinema film with the power of recall in picture form of the exposures to stimuli and events, must be thought of as consisting of millions of little paths,

each of which, while distinct, has communications with other paths. The path from without inward represents a point in the brain where an impression was made through any of the senses, a continuation through the brain and through nerves of two kinds: one the nervous system which prompts muscular action, the other, more important for the understanding of our problem, nerves associated with glands and the internal organs of the body, which internal organs and which glands act in a specific manner according to the stimulus. This latter mechanism is the mechanism of the instincts and the emotions, the autonomic nervous system; the former mechanism produces those muscular responses which are likewise typical for the various emotions. This latter action creates a smile, a frown, the tearful face, the attempt to strike a blow, the warding off of a blow, flight, etc.

This outward physical manifestation as well as the impulse to do must be kept distinctly separate from the processes of internal reaction in the heart, blood-vessels, blood-stream, etc., and from the action of the internal secretory glands which, as stated before, act typically in association with the emotions produced by stimuli.

Now the whole problem depends upon several facts which must be held in mind. (1) Repetition of the same stimuli may sensitize the path and sensitizes the reaction. (2) This sensitiveness of any path or paths may be diminished by switching the course of the stimulus into other paths. (3) To whatever degree any path or paths are made oversensitive by use they overshadow other paths and attract into the sensitized paths a stimulus, which, without this element of enhanced attraction or invitation, might have gone into some other path. Therefore any instinct, if it is stronger than another, is so because the mechanism of attraction is more powerful in one field of paths than in other fields of paths. Let us remember that at the end of each path is an endocrine, or endocrines. And since everyone is born with instincts and emotions of varying types and degrees of intensity, stimuli follow what is for that individual the course of least resistance or greatest attraction. Now it is possible to develop and widen and sensitize paths by use. It is possible to anesthetize paths by disuse. It is possible by diversions or switches to alter the course or path which any stimulus may follow, and the ability to accomplish these results depends firstly on the inborn physical qualities and on the effects of treatment or training, and subsequently on what we call self-control. In other words, during childhood and the early years, the parents should be the switchmen and the flagmen; during the same period and, of course, much more so as the child grows older and in adult life, the individual concerned is his own switchman and flagman.

The whole problem of dreams depends to a great extent upon the theory of a reverse of this action; that is, any endocrine activity which is or has been the end result of a stimulus associated with an experience or an emotion may by a reverse of the primary course be responsible for the recall of the registered stimulus or its like, though this resemblance may not always be apparent. Hence the term, symbolism.

The tremendous error of the Freudian idea is the stress that it laid on the sex instinct. It is a strong instinct, but other instincts and emotions are of as great if not greater importance in their association with neuroses and psychoses. The latter are produced much more often by changes in the thyroid, in the suprarenals, in the parathyroids, or especially in the pituitary. The contra-suggestive individual is of all the people in the world most likely to be unhappy. The individual whose instinct of subjection is all too marked may find his lot in life extremely difficult. The too suggestible individual is readily led into temptation. A person with the gregarious instinct strong in him and who spends his or her life on an isolated farm, is apt to be unhappy, and it is the gregarious instinct which takes him or her from the farm to the large city. It is this gregarious instinct which keeps millions of people in miserable surroundings and under the influence of unwholesome conditions when otherwise they would be much happier on a farm. The instinct of curiosity, much as it leads to scientific investigations, leads to most erroneous views of sex questions unless correct interpretations and explanations are given, and if the Freudians have done one thing more than many others which have done harm it is that they have laid such stress on one instinct and have created misunderstandings and morbid interest in that phase of life which should not play an all important part in the thoughts of the individual. I know many men whose nervousness and irritability are due entirely to the worry about their stock exchange speculations; I could, therefore, if I wished, prove the worry and annoyance and wear and tear on their endocrines to be, as it really is, the responsible factor for the neurosis. I know women who are depressed and unhappy because they have no children. I know women who are nervous and irritable because they have a domineering, contrasuggestive, or unusually self-assertive husband. I know many women who are nervous because of the problems associated with the training and care of their children. But if any or all of these have dreams at one time or another of a sexual nature, are we to forget all the innumerable endocrine plays on instincts and emotions, and center our thought on the sexual sphere, even though, as is the case, the sexual sphere is likewise in many instances responsible for neuroses and psychoses? And, best of all, when we explain to a patient that she or her child is at one or various times under the stimulation of the sex hormones of the numerous endocrines of the body, and that some of her dreams may in many ways be the end result of such activity, do we not remove from such patients the fear and feeling that they are mere animals, unmoral or immoral? And if we are correct in our explanation can we not prescribe gland extracts which inhibit or modify this overactivity? We can.

When a person is exhausted by normal work or exercise and sinks into a refreshing sleep, his endocrines, so far as they are associated with volitional stimulation, likewise go to sleep, particularly the pituitary and thyroid. If an individual as a result of reading, mental activity, or aroused emotions fails to fall asleep, some endocrine activity is stimulating those areas and functions of what are called the upper consciousness, and since it is active, it

continues to exert control over the subconscious. A thyroid activity stimulating cerebral action, the activity of any other endocrine which does the same or makes one conscious of certain emotions, likewise stimulates the upper consciousness, and it often takes people hours to fall asleep. Coffee keeps people awake since it stimulates the thyroid; alcohol may do the same. If you do fall asleep, without cerebral and endocrine activity previously aroused by worries, anger, fears, joys, unsatisfied longings, etc., and the upper consciousness is no longer stimulated, the subconscious sphere may likewise be inactive; you sleep well, you have no dreams, and you awaken refreshed because, at the same time that the upper and lower spheres of consciousness have not been irritated into activity, the sleeping endrocrines have been exerting only a normal, wholesome effect on the other functions of the body and cell repair has taken place. But while the upper consciousness is, so to speak, at rest, even if not completely, and you are, as we call it, asleep, if the endocrines exert their play on what we call the subconscious state, you have all varieties of involuntary recall, and since volitional control is wholly or partly absent, the activity of the subconscious may be likened to the saying that "While the cat's away, the mice will play."

Let us make a comparison. During the day the servants in the household may obey your orders and do what you ask them. When once their work is over their behavior below-stairs is like the action of the subconscious state. You may not know what they are doing, but you may hear something if their play or behavior is sufficiently active or exuberant to carry sound to your ears.

Another comparison. An officer drilling a company receives prompt response to his orders. If he and his company retire at night and go to sleep all is peaceful. If a hundred men be given leave for an evening, are left to their own resources, there may be a hundred different forms of behavior if each does what he likes. Several groups may join in different diversions or all may do the same thing in concert, but they certainly will not drill as they did during the day. If the officer is away he knows nothing of what is going on. If he is with them, and during these hours he attempts no disciplinary control over their enjoyments and behavior, their behavior may be likened to the action of the subconscious state while the upper consciousness is out of action so far as control is concerned. These comparisons are supposed to represent the various types of dreams resulting from endocrine stimulation of the subconscious sphere by endocrines still awake. While any endocrine is exerting its action on the subconscious, of course it may also be acting on the upper consciousness, thus calling its attention to what is going on below, and this is called a dream. And as the various endocrines are associated and brought into action by different instincts and emotions, some purely mental, some those of anger and fear, some sexual, etc., the reverse action or recall will be along the lines of the mental, fearful, sexual, etc., according to the endocrine element or elements which are acting at the time of the dreaming.

When you give bromide to a patient you are diminishing the sensitiveness of the paths, the endocrines, and the cerebral centers. When veronal makes a patient sleep it does so because it, so to speak, puts the endocrines (very frequently the thyroid and pituitary), which are stimulating the upper consciousness, into a state of diminished activity. Therefore, veronal in very small doses is an excellent drug for hyperthyroidism.

When a patient after several hours of sleep awakes and cannot fall asleep again, some endocrine is responsible for the rousing of the upper consciousness, and if we find, by questioning, the nature of the dream which aroused the patient, or the thought or emotion which is now present during this waking state, we can readily discover which of the endocrines are hyperactive at this time. Pain arouses by messages to the cerebrum. Some day when we have analyzed the exact physiological action of the various hypnotics and soporifics we shall prescribe more intelligently for sleeplessness unless, as is probable, endocrine therapy will accomplish this result better.

In pregnancy many patients suffer from nausea and vomiting. Those who do not suffer in this way are, as a rule, rather drowsy or sleepy. In the former there is a rousing of the adrenals, the posterior pituitary, and the thyroid. In the latter there is a relative diminution of activity of the endocrine glands, especially the hypophysis, and we have the mildest form of hibernation produced by placental secretion. If you administer only a few drops of chloroform to a patient in labor after the injection of pituitrin, the uterine contractions become less severe and recur at greater intervals. Therefore, chloroform inhibits the posterior pituitary or its action. Castor oil and quinine have a tendency to bring on labor pains if administered about the expected time of labor. Therefore, they either act directly on the uterus or stimulate the posterior pituitary, or sensitize the uterus to the contractile influence of pituitary secretion. Morphine puts most patients to sleep, but it stimulates some and keeps them awake. Therefore in the former it acts on the upper consciousness and on the endocrine activity, and in the latter it stimulates both. Drug sleep is the result of the artificial hibernation produced, whereas normal sleep is normal hibernation or normal endocrine rest. The endocrines, so to speak, go to sleep. Alcohol keeps some patients awake and in very small doses it puts others to sleep. Alcohol, given in varying degrees up to intoxication, removes the control exerted by the upper consciousness and the anterior pituitary, and brings out evidences of the instincts and emotions in different individuals according to the endocrines most stimulated, and we may have an individual fearful, tearful, joyful, pugnacious, quarrelsome, amorous, etc.

I have used ovarian extract, whole gland, always and rarely corpus luteum extract. Corpus luteum extract counteracts the influence exerted by whole ovary, for in the latter the interstitial part (ovarian residue) is of greatest importance. It is the glandular part and the corpus luteum which stimulates the adrenal medulla and the glandular thyroid which are the two gland structures most affected in hyperthyroidism and the nervous and anxiety states of women. The interstitial thyroid and the adrenal cortex are of the greatest importance and

these two special extracts will soon be in my hands. Hence I have used the whole suprarenal gland to get the effect of the cortex and have used testicular extract as an added help where adrenal cortex action was desired. I am now paying attention to the parathyroids whose importance is certainly very great. The question of the pineal is difficult, but some of my cases with suggestion of the Mongolian eyes and face with or without obesity are being watched along these lines. The same balance or question of balance as exists in the endocrines above mentioned exists within the thyroid, the pancreas, the kidneys, in the muscles and bones, in the brain, and in all the structures of the body. As I observe, in cases now being studied, kidney diseases are the result of endocrine abnormality. Goodhart and others have made important observations in muscular dystrophies. If we apply to muscles the question of balance between the muscle bundles on the one hand and the connective and elastic tissue fibres on the other hand we see that the same relation holds good as is observed in fibrosis, fibromata and myomata of the uterus. The same relationship holds in kidney diseases, overgrowth of the interstitial tissue, or of the glandular portion or of both. As to tumors, benign and malignant, they are all due to endocrine action. We shall find that carcinomata are due to different endocrines according to their situation: breast, pylorus, coecum, sigmoid, uterus, etc. The neuroses and phychoses are endocrine as to cause. In a subsequent paper the curative action of placental extract, for example, on pituitary psychoses and on other states due to the pituitary and other glands, will be reported. In conclusion let me make this prophecy. In five years there will be few mental defectives (new), few feebleminded (new), few insane (new), few tumors (new), few cancers (new), few diabetes (new), few renal diseases (new), and so on. Since they are due to endocrine aberrations they will be corrected in their earliest stages by endocrines. When the next war comes, if it does at all, soldiers before going over the top will not be given alcohol: they will be given endocrine cocktails and the adrenal cortex will be an important ingredient. And if the world, in the near future administer to its diplomats, to its highest officials, to its legislators, and to its people the proper endocrines, especially anterior pituitary, and inhibits the adrenal cortex a little bit, there may be no more wars.

Woman is a combination of glandular ovary, corpus luteum, adrenal medulla, glandular thyroid posterior pituitary, and mammary acting much more energetically and specifically than in man. That is why they have hyperthyroidism and the numerous emotional conditions which we have so long and so erroneously labelled "neurasthenia," "hysteria," when they really are "neuroses," "psychoses." And if we finally conclude, as is probable, that one part of a gland acts through the vagus, and the other part through the sympathetic then the question of balance is of greatest importance.

Many of the statements above made cannot as yet be substantiated by laboratory investigation. They have, however, stood the more convincing test of therapeutic application.

I have had, in editing this paper, the encouragement of Dr. S. P. Goodhart. Since so many of the endocrine conditions seen in gynaecology lead into the realm of neurology and psychiatry, his approval lends an additional touch of authority to much that has been said.

A SIMPLIFIED AND SAFER HYSTERECTOMY.

By HOWARD CRUTCHER, M.D.,

JOLIET, ILLINOIS.

Cancer is one of the scourges of mankind. If all the facts were known, or could be known, it might well be questioned whether uterine cancer is not the commonest manifestation of that disease. I am satisfied that many women pass away from the remote results of this malady whose real condition is hardly more than suspected, far less demonstrated by accepted scientific tests.

Fortunately, the uterus is so situated that its total removal in uncomplicated cases may be effected safely, easily and rapidly; and, more fortunate still, the ultimate results of such operations afford the highest cause for gratification to the lover of scientific progress.

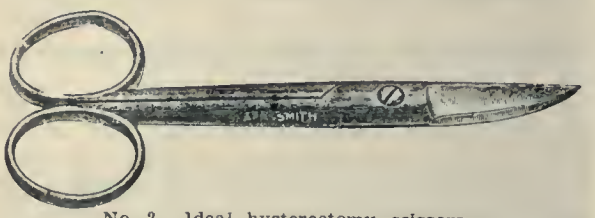
Pathologists, without notable exception, are agreed that nearly all cases of uterine malignancy originate in the neck of that organ. The prompt and complete removal of the whole uterus through its natural outlet possesses such immeasurable advantages over the more complicated and dangerous

No. 1.—Volsellum for drawing the uterine cervix into the field.

costopubic route that it should always be chosen in the absence of positive contraindications. It is my present purpose to describe with some minuteness the uncomplicated operation as I have performed it for many years, a single operative death marring an otherwise exceptional record of success. It is manifestly impossible within the limits of an acceptable paper to deal even superficially with the numberless complications that frequently confront the hysterectomist. Few cases, indeed, are wholly free from some complication, either trivial or serious, but I shall purposely abstain from discussing them at this time. With the ideal operation clearly in mind, the various complications may be the more readily explained and their proper treatment the more adequately set forth.

The tincture of iodine is applied freely to the parts. The natural outlet being spacious, broad Sims retractors (flattened in the blades) are inserted above and below, exposing to view a tiny spot of cancerous tissue situated near the mouth of the womb, extending slightly into one of the cervical lips. The neck of the uterus is seized through healthy tissues with strong volsellum forceps, and drawn forward until flush with the lips of the vulva. Under no circumstances must the diseased area be punctured or incised with any instrument. The neck of the womb is drawn upward, and with a pair of short, heavy, sharp-pointed curved scissors the mucous membrane is divided by a circular

incision down to the firm wall of the uterus, beginning about half an inch from the os uteri. Around the lower half of the circle the incision may safely be carried much further from the uterine mouth than the near presence of the bladder would

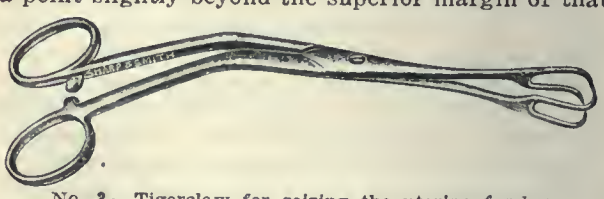


No. 2.—Ideal hysterectomy scissors.

permit above. With his finger the operator presses into the loose connective tissue of the uterine envelope, using the scissors upon whatever fibrous bands may resist his progress upward, always cutting toward, and not away from, the muscular coat of the organ. At this point curved T-retractors are placed upon the severed vaginal mucous membrane, that tissue being properly drawn aside to afford a better view of the uterine connective tissue.

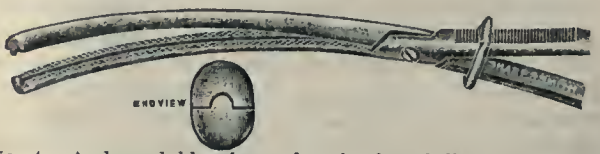
The supreme danger in hysterectomy is from bleeding. The blood supply of the womb passes wholly through the broad ligaments, one situated at each side of the organ. The immediate object now is to expose the sources of the blood supply, isolate them, clamp them securely, and complete the work by cutting away the uterus. For convenience, the left pedicle is dealt with first. The bladder and the much-dreaded ureters are readily freed from all uterine connections by the advancing finger. Just above the utero-vesical juncture the thin peritoneal coat of the *fundus uteri* is punctured, the surgeon sweeping his finger freely within the peritoneal cavity, making careful mental note of all important landmarks. (About this time a cystic, although not a healthy, ovary is quite liable to make its presence known.) The uterorectal peritoneum is next punctured, very close to the uterus, with a pair of large, Kocher forceps, this opening being rapidly enlarged with the finger. No important blood vessel has thus far been met with, and all oozing has been promptly controlled by dry sponging.

A tigerclaw is now inserted through the superior (upper) peritoneal opening, the fundus is seized transversely and drawn into full view, projecting well between the superior labia. The left broad ligament is now in plain sight and may be quickly secured as follows: Guided by the left forefinger, inserted from above, the lower blade of a dependable clamp is introduced below and behind the ligament, and pressed upward until its tip appears at a point slightly beyond the superior margin of that



No. 3.—Tigerclaw for seizing the uterine fundus.

structure above. The surgeon now satisfies himself that the tissues of the pedicle, and these tissues only, are within the grasp of his instrument, one of the labia or a fold of vaginal mucous membrane often requiring retraction from the blades of the clamp. The superior blade of the clamp is always in plain view. The blades of the instrument are cautiously and patiently driven home by compressing the handles, which are now locked securely. The pedicle is next divided between the clamp and



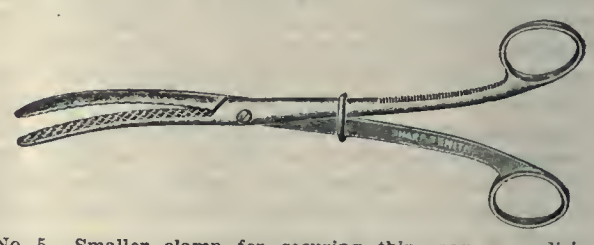
No. 4.—A dependable clamp for the broad ligament. Note its long, wide blades, and its simple, unfailing lock.

the uterus with a scalpel, the operator bearing well in mind when using the knife the heavy shrinkage that pedicles undergo after division. The right pedicle is next treated in like manner, when the surgeon makes a minute inspection of his whole field of work to make certain that he has overlooked no active bleeding point. Adventitious vessels do appear occasionally, in defiance of all precedent, but are quickly and effectually suppressed by the application of heavy Kocher forceps. The use of these forceps saves much valuable time and tedious work involved in the application of ligatures. Healthy ovaries are not disturbed. A cystic ovary may be drained, treated with pure alcohol, and returned to its place. A coil of intestine rarely appears, although a diseased vermiform appendix has been clamped and removed under such conditions. The omentum is a more frequent visitor to the field, and the discharge of a small slough of omental tissue some days later need cause neither surprise nor alarm.

The surgeon now looks upon a dry, clean field, and carefully adjusts each clamp to its proper pelvic quarters.

A large square of plain gauze is now spread over the operative field, its center being pressed deeply into the vaginal canal to a point somewhat beyond the original circular vaginal incision. Into this pouch are pressed strip after strip of gauze soaked in a solution of adrenalin, until a snug Mikulicz drain has been properly placed in position. The projecting handles of the clamps are now wrapped in a loop of gauze, a heavy absorbent dressing applied, all being retained in place by the application of a snug bandage of gauze or muslin.

The blades of the clamps lie, of course, outside the vaginal packing, and the serous drainage finds a ready outlet along the course of the instruments. The external dressings should be changed as often as necessary. It is advisable to catheterize the pa-



No. 5.—Smaller clamp for securing thin, narrow pedicles.

tient every six hours. The pulse ranges between 70 and 80, but may rise higher unless the bowels are kept clear by saline enemas after the third day.

Contrary to a widespread misconception, the clamp operation is not more painful than other

methods. The gauze packing, on the other hand, is always more or less distressing, no matter what means may have been taken to secure the pedicles. Not infrequently the administration of some anodyne is indicated until the pressure from the packing is relieved.

After forty-eight hours the clamps are unlocked but are left in place for a few hours, when they may be withdrawn readily by gently opening the handles. Any Kocher forceps that may have been left upon small vessels may be removed at the same time. Some of the strips may be taken away with the clamps, but the gauze pouch may be left until the fifth day or later, its removal being greatly facilitated by irrigation with some mild medicated solution. Repacking is applied as circumstances may require. Convalescence is usually complete within two weeks.

By way of comment it may be said that the highest point of danger will be found in the upper half of the broad ligament, when all risk of injury to the trunk of the uterine artery, the bladder and the ureters has passed away. In a former paper (Some Observations on the Blood Supply of the Uterus, etc., MEDICAL RECORD, July 20, 1918) I have treated the surgical anatomy of the uterine artery somewhat more intimately, but in no case does this vessel normally penetrate the true uterine substance. In all cases of doubt the operator will find his path of safety to lie in close contact with the muscular wall of the womb.

The use of multiple clamps upon the pedicles is to be distinctly condemned. A single dependable instrument, full of spring in both blade and handle, of sufficient length completely to overlap the widest pedicle, the tip closing slightly before the base, secured by an unfailing lock, is the ideal instrument for this important work. My only disaster in this operation may be traced to the use of small, worthless clamps, which tore the treacherous tissues, which a single, well-conceived instrument would have held perfectly. This death, however, occurred in a case blazing with complications, and hence does not fall properly within the scope of this paper.

In all operations for malignant disease the surgeon, of course, will apply his clamps as far as practicable from the body of the uterus, but as all the tissues involved are in plain sight this action imposes no additional danger to recovery. I know of few things in surgery more dangerous than the clamping of important tissues in the dark and trusting to luck, when the eye alone is the safe guide. In a respectable list of hysterectomies, some of them notable for serious operative difficulties, I have no important accident to record, either during or following the operation, save the single death from bleeding already mentioned. Annoying cicatricial contractions of the vagina have not followed in any case, so far as I have heard. Surgical shock is certainly most merciful to us in this field of work, even in cases remarkable for operative difficulties.

So far as the ultimate results are concerned, I regret to say that much testimony of a wholly favorable character is purely negative. I have found it practically impossible to induce most patients to favor me with even so small a courtesy as an annual report. One patient closed her case as follows: "If any trouble comes up you may be sure that you will hear from me at once." This case is typical of scores of patients who have no scientific interest whatever in uterine cancer so long as they are themselves free from its ravages. Some altogether surprising cures must be credited on positive evidence to the radical operation. In any case of doubt my inclination would be to remove the uterus whenever justified by the principles of rational surgery. Those familiar with the horrors of uterine cancer in its later revolting stages will be disposed to assume all honorable responsibility in attempting to avoid one of the most pitiable sights within the whole range of professional experience.

My acknowledgments are due to Messrs. Sharp & Smith, Chicago, for their untiring zeal, patience, and skill in the preparation of the instruments shown in the accompanying illustrations.

SYMBOLISM.

BY H. LAVESON, M.D.,
NEW YORK.

THROUGH the study of dream symbolism we possess a series of general statements and of particular observations which are quite certain. There are symbols which practically always have the same meaning: Emperor and empress always mean the parents; room, a woman, and so on. The sexes are represented by a great variety of symbols, many of which would be at first quite incomprehensible had not the clues to the meaning been often obtained through other channels. There are symbols of universal circulation found in all dreams, of one range of speech and culture; there are others of the narrowest individual significance which an individual has built up out of his own material. In the first class those can be differentiated whose claim can be at once recognized by the replacement of sexual things in common speech from others whose sexual references appear to reach back to the earliest times and to the obscurest depths of our image-building. The power of building symbols in both these special forms of symbols has not died out. Recently discovered things, like the airship, are at once brought into universal use as sex symbols.

It would be quite an error to suppose that a profounder knowledge of dream symbolism would make us independent of questioning the dreamer regarding his impressions about the dream, and would give us back the whole technique of ancient dream interpreters. Apart from individual symbols and the variations in the use of what is general, one never knows whether an element in the dream is to be understood symbolically or in its proper meaning; the whole content of the dream is certainly not to be interpreted symbolically. The knowledge of dream symbols will only help us in understanding portions of the dream content, and does not render the use of the technical rules previously given at all superfluous. Dream symbolism leads us far beyond the dream; it does not belong only to dreams, but is likewise dominant in legend and myth, in wit and in folklore.

Let us take, for example, the national flag. That

the flag is a symbol needs no argument. It stands for, represents, symbolizes, the nation. That is almost all that can be said for it in general, but further than that it stands in each individual's thinking for what the nation means to him. The idea of the nation, itself a symbol, means one thing to one person, another thing to another person. To one, it means protection; to another, community of interests; to still another, a certain geographical area; to one, it stands for a military unit; to another, it means right, honor, loyalty, etc. Every individual gives his own particular touch to the concept nation, and so for him the flag has that special meaning. And yet, with all this infinite diversity, the flag is able to unite all that is held in common, all these various ideas and feelings meet on a common basis which is nucleated in the national emblem, and at large gatherings of people one can see how they are swayed by it, how in one common sea of feeling they all react in practically the same feelings, the same emotions, the same sounds as they sing a national anthem. There is no need to dilate upon the obvious, and more than mention the immense amount of energy which may thus be liberated; the particular point of emphasis, however, is that in some way this enormous energy is wound up in the symbol. The symbol is the transmitter and transmitter of energy at this level, just as the reflex arc, the ion, or the lever are at lower levels.

First, as to the wide latitude of usefulness of the symbol. Consider the symbol money, for example. Money represents accumulated energy. Work of whatever character, unintelligent, physical labor, or highly intellectual, is reduced to the common standard of money value, and so the energy which an individual has to give in the form of work he, so to speak, turns into the energy symbol money, and this symbol can be exchanged for any one of innumerable kinds of energy carriers—for bread and meat, for machinery, for manufacturing purposes, for books of learning, for maintaining a home; in short, for an infinity of things which have as their function the maintenance and preservation of the individual and the increase and extension of his power and influence.

Money, as a symbol of energy which could be exchanged in trade, has existed from the earliest times. The energy has been concretely represented by all sorts of things—from the crude forms of the primitive man, the shells, beads, and wampum, to the highly elaborated gold and silver coins and bills of the present day. The underlying principle, the common meaning, the unconscious origin, has always been the same. It would be hard to imagine a more adjustable, usable, practically available energy transmitter and one at once so sensitive to all the circumstances in the midst of which it exists. Witness the fluctuations of foreign exchange in response to rumors affecting the possible solvency of a nation (energy).

In order that the meaning of symbolism may be understood, in the broad sense in which it is used, it is essential to keep in mind the nature of the relation between the process of thinking and the forms which are used in expressing that process. The process is one of continuous unremitting change—the forms of expression are the results of efforts to catch the process in the very act of becoming; they are snapshots which try to fix the process in forms that can be read.

The fundamental principle of symbolism is that anything may symbolize anything else, and in a given instance the only way to find out the meaning of a symbol is to make inquiry of the subject expressing it. The psychologist cannot tell offhand what a given symbol may mean in a particular instance. It may mean one thing at one time and another thing at another time; it may mean one thing to one person and another thing to another person; it may or it may not have the usual significance.

The next important principle is self-evident. The symbol must be chosen from the mental content. When one, so to speak, is looking about for an appropriate symbol he is limited in his choice to the content of his own mind. Not only may a given symbol mean one thing one time and another thing another time, but the same symbol may be used by different persons in quite different ways. If several persons will look at a radiator, for example, they will probably treat that radiator differently in their thoughts, depending on their previous experiences. One may be reminded of the rise of temperature in a fever; another may think of the steam and the steam may call up an ocean voyage on a steamship, with all the complex associations of that voyage; another may think of the warmth of friendship, another of efficiency as expressing the work of the radiator, while still another may be reminded by the corrugations of the corrugated paper about a book recently received from the publishers, its contents, etc. (association of ideas). The possibilities are endless. And finally the manifestness of the symbolism is in direct proportion to the poverty of the apperceptive mass and the consequent concreteness of expression. Darwin records the instance of a child, who, seeing a duck on the water, called it "quack." From this on he called all flying things "quack"—birds, insects, especially house-flies, and also fluids—water and wine. Finally, when a sow was shown him, he called this also "quack"; "quack thus came to mean such different things as flies, wine, and coins. The word "quack" was used originally to express the duck on the water, so it comes to be applied to all flying things and to all liquids. When the word is extended to include coins, it is not because of a conceptual generalization, but as the result of an associative transference due to the figure of the eagle on the coin, which is already known as "quack." Because the field of perception of the child's consciousness is very narrow, all of the characteristics, partial perceptions, are possible, and appear in the perceptual complex, while other characteristics are excluded. Thus the thinking tends to relative concreteness.

Keeping in mind the energetic conception of the libido, we can understand then that a symbol is an expression of ourselves. The particular person or thing is used as a symbol because it represents our way of thinking and feeling about the fact it stands for. It stands, therefore, for ourselves, or so much of ourselves as is represented in our feeling attitude toward the thing symbolized. The patient who, in a dream, symbolizes the sexual by a

wild animal, has not only made a symbol for sexuality, but has also expressed in that symbol an element of his own sexuality recognized as wild.

THE PRESENT STATUS OF GENERAL ANESTHESIA FROM THE HOSPITAL VIEWPOINT.

By SIMON D. EHRLICH, M.D.,

NEW YORK.

ANESTHETIST TO BETH ISRAEL, ST. MARK'S, AND JEWISH MATERNITY HOSPITALS.

The subject of anesthesia presents the following topics of especial interest to hospitals: 1. The administrative requirements of the general anesthetic. 2. Who should give anesthetics? The prerequisite requirements. 3. The staff member as the anesthetist. 4. The interne as the anesthetist. 5. The trained nurse as the anesthetist.

The Administrative Requirements of the General Anesthetic. (*a*) *Nitrous Oxide and Oxygen:* No modern hospital can consider its anesthesia department complete without suitable provisions for the administration of nitrous oxide, with or without ether. The advantages resulting from its use are many. The induction is rapid and very pleasant; it is safe; recovery is rapid; there is little or no irritation of any of the organs; after-effects are completely absent or greatly diminished; complications are reduced to a minimum.

Most institutions find it more convenient to buy their supply of nitrous oxide. Hospitals, however, which use very large quantities of this gas, or those which contemplate changing to larger and more modern buildings, would do well to consider the question of manufacturing their own supply. While the initial investment for the installation of the plant is quite large (according to the Lakeside Hospital reports it is about $3,000), it would pay for itself in the course of time, and there would be the great advantage of a knowledge of the absolute purity of the gas.

There are two distinct types of apparatus for the administration of nitrous oxide with oxygen—one delivering a continuous flow of the gases, with or without rebreathing, and the other giving an intermittent flow, with rebreathing. It is a matter of opinion among anesthetists which type is the better. My own preference is for the method of intermittent flow of gases with rebreathing, because it eliminates the large, cumbersome tanks, the necessity of reducing valves, and freezing troubles; it is more economical; and the rebreathing, I believe, is decidedly beneficial. Of these two types of apparatus there are, at present, any number of different makes, each one claiming special advantages. It is not a matter of great importance which of these is chosen. One anesthetist will give a good anesthesia with the apparatus which he is accustomed to use, while another will use a different apparatus and get the same results. It is simply a question of being expert in the use of a given apparatus. I prefer the apparatus which is so equipped that the ether can be added drop by drop, as with the Coburn or Flagg instruments. The various attachments for warming the gases are not important because, by the time the gases reach the larynx, they are warmed to body temperature.

(*b*) *Insufflation Anesthesia:* In using ether (or rarely chloroform) in operations on the head, neck or chest, it is generally recognized that the most satisfactory method of anesthesia is by means of insufflation. In head and neck surgery the anesthetist can keep out of the field. In operations in and about the mouth and nose, which would otherwise require the intermittent use of the mask, it is ideal. In chest work, it permits keeping the lungs inflated when necessary. In fact, where ether only is to be used, the insufflation method may be employed to advantage because the anesthetic vapor is delivered to the patient, whereas, in the usual inhalation method, the patient must use his own respiratory efforts to obtain the anesthetic vapor. This is especially important in operations during shock, as mentioned by Crile, in observations from the front.

This method requires an apparatus, preferably motor-driven, which will deliver air under regulated pressure; this air under pressure, by means of proper connecting tubes, is then made to pass partially or completely through a bottle containing the anesthetic (ether or chloroform, or both), and from here by tube into the trachea, pharynx, or buccal cavity.

The ideal apparatus to date for this purpose is the Konnel Anesthetometer, an instrument which delivers automatically "a known volume of accurately measured percentage of ether vapor" evenly throughout the administration. This apparatus is not generally used because it is very expensive. There are, however, several moderate-priced instruments on the market, which, while not so perfected, are very practical for insufflation purposes. A good many of these are so arranged that, in addition to the insufflation, there is an extra attachment for suction; this is a great help in most of the nose and throat operations.

(*c*) *The Open Method:* While a few of the large clinics still use exclusively the so-called open method of ether administration (really a semi-closed method), most of the large hospitals now use the closed method with nitrous oxide, with or without oxygen for the induction. However, the open mask still has its field of usefulness. It is best for infants and very small children; for very adipose subjects, especially those with short necks; for the very old, especially those with wheezy chests, cyanosis or very marked arteriosclerosis, who do not, as a rule, stand the closed mask well; where chloroform is to be given. Internes who are just beginning the course in anesthesia should learn the open method before attempting the use of the closed. The best mask for this purpose, I believe, is the Yankauer mask.

As part of the requirements in any method it is necessary for the anesthetist to be provided with a suitable table, or tray attached to the operating table, equipped with a mouth gag, tongue forceps, wedge, breathing tube and anesthesia chart.

Who Should Give Anesthetics? The Prerequisite Requirements.—It is absolutely essential, in my opinion, for the anesthetist to be a physician, one who combines a general knowledge of medicine with a specialized knowledge of anesthesia and the technique necessary for handling various apparatus. A general knowledge of medicine is indispensable for

a thorough understanding of the following: (*a*) The physiology and pathology of the heart and blood vessels, lungs, kidneys and other organs of the body. (*b*) Metabolism and its diseases—diabetes is especially important, as diabetics are very poor anesthetic risks. (*c*) Acid intoxication, the action of anesthetics in inducing acidosis or aggravating it when already present, and the means of combating this condition. (*d*) Shock—its nature, causation, manifestations, prevention and treatment. (*e*) The various reflexes and their indications. (*f*) The factors contributing to the patient's condition—for example, given a patient with a depressed state of respiration, the anesthetist should be able to determine whether this condition is the result of depth of anesthesia or outside influences, such as operative manipulations in the upper abdomen, or a preanesthetic dose of narcotic. In all these instances a general knowledge of medicine makes it possible for the anesthetist to exercise his judgment for the welfare of the patient. The anesthetist's opinion of the patient's condition is helpful to the surgeon during operation, and in recommending preoperative and postoperative care. The surgeon who works with an expert anesthetist comes to rely upon his judgment as an important factor in the welfare of the patient. It is also essential to know the physical properties and physiological action of the various anesthetics used and their individual indications and contraindications.

The Staff Member as the Anesthetist.—The large hospitals have begun to recognize the need of a visiting anesthetist, a physician who devotes his time exclusively to the subject of anesthesia. This work is of such importance that it should be accorded a department of its own, with an established head, who shall assume the responsibility and control, and who shall have a position on the medical board in the same capacity as the heads of the other departments.

The duties of the visiting anesthetist should include the practical instruction of the internes assigned to anesthesia service; instruction in the use of the various methods of administration which obtain in the particular hospital; the proper care and selection of the agents, their properties, the advantages and disadvantages of each; preoperative and postoperative care and treatment; and the keeping of careful records of all anesthesias, or charts provided for the purpose. The staff member supervises the interne during routine work. Where necessary, however, in difficult and serious cases, he administers the anesthetic himself.

The Interne as the Anesthetist.—At the present time the system of medical education is such that the student receives very little theoretical, and little, if any, practical instruction in anesthesia. The hospital should afford every interne the opportunity to supply this need in a regular course of anesthesia of four to six months' duration, during which time he gives all the routine anesthesias under supervision and instruction by the staff anesthetist. It is advisable to have more than one interne doing this work during the same period so that one man relieves the other. The best time for the interne to get this instruction, when the term of service permits, is during the second half of his first year's stay at the hospital. By that time he will have received a more practical knowledge of physiological and pathological conditions of the various organs of the body, and will therefore be more ably equipped for this course.

The Trained Nurse as the Anesthetist.—Considering the prerequisites mentioned above, I maintain that a nurse is not fully competent to administer anesthetics. She may be trained in the mechanical processes of the administration, and may even have had a few months' instruction is physical diagnosis. But this at best can give her only a superficial experience, and does not prepare her to meet the conditions with the matured judgment which comes only with a thorough knowledge of medicine. She is no more qualified to do the work of an anesthetist than a nurse with operating room training and a superficial knowledge of anatomy and the mechanical skill which has enabled her to master the steps necessary to open an abdomen and remove an appendix, for example, would be qualified to do the work of a surgeon. The matured judgment which comes only with a general knowledge of medicine is wanting in each case. The fact that nurses administer anesthetics in a few large clinics is by no means proof that it is a good thing either for the patient or for the institution. Indeed, a hospital which entrusts work of this nature and importance to a nurse assumes a grave responsibility. Justice to the patient demands that he be served with the utmost skill, not only in the mechanical administration of the anesthetic, but in the ability to cope with any emergency which may arise during the anesthesia. During wartime, in communities where so many anesthetists were called to the front that it was impossible to get physicians to take their places, it may have been expedient to permit nurses to substitute them; but this should be only a temporary, not a permanent arrangement. If a nurse finds that she is interested in this work, she should study medicine, and so become thoroughly qualified from every point of view.

SARCOMA OF THE ROUND LIGAMENT.

By G. L. MOENCH, M.D.,

NEW YORK.

Although about 140 cases of tumors of the round ligament have been reported in the medical literature, the occurrence of malignant tumors, and especially of such of larger size is quite rare in this part of the body.

As the round ligament passes from the fundus of the uterus downward and outward through the inguinal canal and through the peritoneum to be inserted just outside of the external inguinal ring, the tumors of the round ligament may be situated either inside or outside of the peritoneum. They must, therefore, be classified according to their location as well as according to their pathologico-anatomical constituents.

I consider the classification given by Frankl as good as any. This author divides the tumors of the round ligament (according to their location) into two main groups: (1) Intraabdominal (intraperitoneal) tumors, and (2) Extraabdominal (extraperitoneal) tumors. The second heading Frankl

splits up into three subdivisions: (a) Intravaginal growths that push the posterior wall of the canal of Nuck forward, and are therefore retroperitoneal like the kidney; (b) intracanalicular growths situated between the layers of the muscles without any connection with the vaginal process of the peritoneum; and lastly (c) preinguinolabial growths situated in front of the external inguinal ring or even in the labium majus. It can easily be appreciated, however, that a tumor may at times extend beyond the limits of any one of the above mentioned locations.

In the case I wish to report here, three rather unusual features were the malignancy of the tumor, its large size, and the correct diagnosis which could be arrived at before operation.

The report of my case follows:

Mrs. F. B. J., Hosp. Rec. No. 567, 1915 (Women's clinic of the Univer. of Tuebingen), 39 years old, III-para.—The woman came to the hospital because she had noticed a lump in her right groin for the past six months. It was at first only about as large as an English walnut, but had grown rapidly in size so that when she came under observation it was as large as a grapefruit. The patient never had any pains or other troubles connected with the development of the tumor. Her menstrual history was normal.

The *general physical status* of the woman was good.

Gynecological Examination: A hard, slightly nodular, somewhat kidney-shaped tumor could be made out on the ramus horizontalis of the os pubis. It extended downward well into the right labium majus and upward for about three and a half inches. The growth could be displaced in all directions for the distance of about an inch. The skin was slightly reddened and adherent to the underlying structures at the summit of the growth, but showed no pathological changes otherwise. The basis of the tumor was apparently broadly connected to the region of the external abdominal ring. The vaginal and rectal examinations showed nothing abnormal. *Diagnosis:* Solid (malignant?) tumor of the right round ligament.

The operation performed on the following day proved we were dealing with a tumor of the round ligament situated in front of the external inguinal ring. According to Frankl's nomenclature it was therefore a preinguinolabial growth.

The tumor was very vascular but could fortunately be freed in the main, without actual cutting. The adhesions between the skin and the tumor at its summit were too dense, however, to be dissected so that a piece of the skin had to be excised along with the tumor. At the external inguinal ring the scalpel also had to be used. It could then be seen that the round ligament which was slightly thicker than an ordinary lead-pencil passed directly into the growth. The round ligament was pulled out as far as the peritoneal cone and there severed without opening the peritoneum itself. Several enlarged glands in the inguinal region and along the saphenous vein were likewise removed. The patient made a good recovery and was discharged well after ten days. She was advised to undergo a prophylactic Roentgen-ray treatment but refused it. At home the patient felt well enough at first but within about four weeks began to show symptoms of metastases in the abdomen, lungs, and cerebrum. She died eight weeks after the operation. An autopsy could not be obtained.

Macroscopical Description of the Tumor.—The tumor *in toto* was about the size of a grapefruit. It was hard, nodular, and somewhat kidney-shaped. To the summit of the growth the excised piece of skin was attached. The adhesions between it and the tumor were very dense in some places. On the opposite side of the specimen the portion of the round ligament removed with the tumor had shortened to a stump about half an inch long and almost as thick. The fibers of the ligament merged without any perceptible demarcation directly with the new growth. Transection of the specimen showed a rather tough growth with a slightly yellowish cut surface which contained some softer, marrow-like looking areas. At the lower pole of the tumor a succulent bloody area about the size of the palm of the hand could be seen. The limits of this area were not distinct but merged gradually with the surrounding tissues.

The lymph nodes which had been removed formed a small grape-like bundle of glands and fat the size of a large walnut with the individual glands about as large as small beans.

Microscopical examination showed that the main part of the tumor consisted of a myofibroma whose connective tissue had undergone hyaline degeneration in many places. The (unstriated) muscle fibers were scant. In some small areas however the myofibromatous tissue had been replaced by a dense growth of small round cells with large very dark nuclei in which mitoses were frequent and not seldom irregular. These dense cellular areas had a definite infiltrating character and destroyed muscle and connective tissue by growing directly into them. In some places actual necrosis had occurred. There could therefore be no doubt that we were dealing with a sarcoma.

There was no evidence of malignancy in the stump of the round ligament attached to the specimen although distinct sarcomatous tissue was present in the direct neighborhood of the insertion of the ligament into the tumor. The increase in volume present in the ligament was due only to a growth of the muscles and the connective tissue fibers normally present here. The individual cells were increased in size as well as in number. At the summit of the tumor where the skin had been adherent sarcomatous changes were very plain.

The inguinal glands were generally somewhat inflamed but showed no malignant changes.

We were dealing in this case therefore with a myofibroma showing definite sarcomatous changes of the small round-cell type. The clinical course of the case showed the extreme malignancy of the new growth. It will be remembered that the woman died only eight weeks after the operation, despite the fact that at the time of operation there had been no evidence of sarcoma present, either in the ligamentum rotundum or in the inguinal glands.

CLINICAL INDICATIONS FOR ENUCLEATION OF THE FAUCIAL TONSIL.

By MAXWELL QUACKENBOS, M.D., M.R.C.S. (ENG.), NEW YORK.

To recommend the routine practice of the tonsil operation upon all children when they attain a certain age as a prophylactic measure directed against rheumatic endocarditis or other infection, is an opinion based upon experimental research confirmed by protracted clinical observation.[1] Certainly the complete removal of the healthy lymph organs does no harm and the incidence of subsequent rheumatic valvular disease is nil.

Selective surgical indications must not, however, be founded upon opinion, but must have for a basis actual disease or malformation of structure, and be

established by a high percentage of cures after skilled operative interference.

The absolute indications for enucleation of the tonsil may be defined regionally. There are four local conditions that indicate enucleation: (1) New growth, (2) the tonsillotomy operation, (3) recurring acute inflammations, (4) hypertrophy associated with Eustachian or nasal obstruction. To these may be added the persistent diphtheria carrier.

Three reflex conditions warrant enucleation, particularly if upon inspection faucial hypertrophy is present: (1) Cough due to an enlarged lingual tag, (2) nocturnal enuresis in the absence of acid concentrated urine, (3) petit mal, or meningism.

The removal of the adenoids by curet is an essential part of the tonsil operation. Chronic infection of the adenoids is manifested in children or young adults by continued frontal headache (sinusitis) or by chronic conjunctivitis or iritis.

Any acquired palsy in childhood (precluding hysteria) is an indication. I believe that the excellent results of enucleation reported in poliomyelitis clearly demonstrate that in such cases the patients are suffering from postdiphtheritic paralysis.

Excellent results accompany enucleation when the child is suffering from chronic otorrhea or middle ear deafness. Personally I think enucleation is an important part of the mastoid operation of antrectomy in children.

No operation on cleft palate, in my opinion, is justified after the age of eighteen months unless the tonsils have previously been removed, their presence being one of the unmentioned causes of failure.

Follicular tonsillitis in middle-aged patients gives rise to gastritis, followed by prompt improvement when the cause is remedied by enucleation. The eradication of oral sepsis, whether it be teeth or tonsils, is too often neglected previous to gastric anastomosis.

Perhaps the most frequent indication for enucleation is cervical adenitis. Any proposed operation for excision of the glands of the neck should be preceded several weeks by the tonsil enucleation and head-fixation with a suitable splint.

There is a group of toxic symptoms resulting from chronic septic absorption from an apparently healthy-looking tonsil. "Arthritis" is an example. Joint lesions or other constitutional symptoms due to a focus in the tonsil are recognized by palpable enlargement of the upper anterior chain of the deep cervical lymph-nodes.[2] The tonsillar afferent node is situated slightly anterior to and below the angle of the jaw, between the internal jugular and the common facial veins.

Enlargement of this afferent node shows that the tonsil is not only diseased but unable to combat any superficial infection, and operative interference which does not completely remove the faucial tonsil with the lingual portion "in capsule" from its sulcus defeats the purpose of the operation. Exposure of the pharyngeal aponeurosis or, if the embedded adherent type of tonsil, removal of the fascia lining the superior constrictor muscle is necessary for strictly uniform results.

While general constitutional improvement is always noted in patients suffering from any debility complicated by enlarged afferent tonsillar nodes after enucleation, as for example tabes mesenterica, before recommending the operation as in arthritis, one should recall that several foci may be the cause of the one symptom. Two male patients upon whom I operated were relieved of their joint pains but returned after a brief interval with lumbago; prostatic massage over a period of nine weeks apparently cured the latent gonorrheal infection of both men.

Of the operations designed for the complete removal of the tonsils, the dissection method of Mr. George Waugh stands paramount.[3] This ideal technique was the first advance in the surgery of the tonsil since R. Wiseman recommended "the way of excision is by making a ligature about the basis of them and snipping them close off with a pair of crooked probed scissors."[4]

In my series of nine hundred cases by Waugh's method there has been no instance of postoperative hemorrhage, all oozing being stopped before the patient leaves the table. In seventy cases I have applied plain catgut No. 2 to the bleeding point caught by an ordinary six-inch artery forceps to achieve this end. The ligature gives a point of attachment to the coagula. My experience has been that it is rarely necessary to remove the posterior inferior turbinates.

The postoperative treatment consists of a gargle of 1 per cent. Chloramine-T, as used by Mr. Waugh, with small doses of ferric iodide, and correction of the mouth-breathing habit, if present, by exercises in the prone position.

The dangers and complications are slight. Two children developed bronchopneumonia, and two with chronic discharging ears required a mastoid operation a few days later. Five adults developed unilateral acute otitis media, and in three of them incision of the drum was required.

There were two deaths. One unfortunately from an overdose of chloroform; the other patient was operated upon for acute mastoiditis superimposed upon chronic otorrhea of many years' duration, and upon the third day showed intracranial pressure symptoms, without localizing signs; postmortem examination revealed a cerebellar abscess.

Changes in the Appearance of the "Brazil Medico."—This representative South American medical journal is greatly changed in its arrangement of material with the present year and now follows closely the plan of the great periodicals of the culture countries. The editorial department in the middle of the number suggests that of the leading English and American journals. Space formerly occupied very largely by society transactions is now devoted to other classifications. The original articles appear to be more clinical in character than in former years, when they were often confined to laboratory activities. A department of news items covers the medical activities in the provinces, and there is now an abstract department. The journal is much larger and printed on better paper than before.

New York, April 17, 1920.

SURGICAL ASPECTS OF TUBERCULOSIS AND SYPHILIS OF THE STOMACH.

BOTH these infections may give rise to their respective specific lesions in the stomach as well as in any other of the viscera, and in most varied forms. Regarded for a long time as very rare, they are now becoming more and more frequent as they are better known and are searched for with greater care. Although highly interesting from the viewpoint of diagnosis they are not particularly so, as far as treatment, especially the surgical, is concerned.

Tuberculous lesions of the stomach are met with in the form of ulcer and pyloric stenosis, usually due to a periulcerous hypertrophy of the region. The tuberculous ulcer is very similar to ordinary round ulcer of the stomach, but has a more chronic evolution, the hyperacidity is more marked, and the lesion extends superficially rather than in depth. The latter peculiarity, combined with the special property of tuberculous lesions of engendering adhesions of the serosa, results in the fact that perforation into the peritoneal cavity rarely takes place. The prognosis is nevertheless bad; the process will not give in to medical treatment and is more prone to occur in advanced cases of the infection.

The surgical treatment—very often contraindicated on account of the miserable general condition of the patient—has usually little effect upon such extensive lesions, contrary to what takes place in simple gastric ulcer, as it cannot reach the fundamental cause of the affection. When the ulcer has not developed stenosis the only surgical treatment is resection—an operation usually too serious to be entertained in these subjects. Tuberculous stenosis is an extremely serious condition and has a worse prognosis than even cancerous stenosis. Medical treatment is perfectly useless so far as a cure is concerned, and operation should be attempted when the patient's condition offers any possible chance of success. The operation may be simply a palliative one, consisting of gasteroenterostomy, which has rarely, if ever, been successful so far as prolongation of life is concerned, the limit of one to two years being the maximum, while pylorectomy is always delicate and very serious in the circumstances. Therefore, tuberculous lesions of the stomach must be regarded as most serious from all points of view and anything like a brilliant result from surgical interference should never be expected.

Syphilitic lesions of the stomach are also represented by ulcer and pyloric stenosis in most instances, although other luetic lesions occur; but these seem to be rather uncommon. The diagnosis is often impossible when the patient does not present other evidences of syphilis, but when the true nature of the gastric process has been recognized an intensive specific treatment is naturally to be resorted to at once. Strictly speaking, there is no surgical treatment of gastric syphilis, any more than there is of luetic manifestations elsewhere. However, a certain number of operations for pyloric stenosis of this nature have been done, especially pylorectomy. It is nevertheless well to remember that many cases of pyloric stenosis may properly be subjected to specific treatment, and this line of treatment should be carried out in every case where other manifestations of the disease show themselves and the patient's condition permits delaying surgical measures for a sufficient time to obtain effects by intensive specific treatment. By so doing, one may have the good fortune of occasionally meeting with a case in which the stenosis will disappear, likewise the pyloric tumor.

THE DANGERS OF INFESTATION WITH ASCARIS LUMBRICOIDES.

THE round worm is a sufficiently frequent finding in this locality so that the great majority of practitioners are well acquainted with its appearance. Most physicians also are more or less familiar with the fact that these worms have been found in the most bizarre locations and that upon occasions they may cause trouble. What is not so well recognized is that these parasites are quite frequently the source of very serious trouble. Some little time since we took occasion to call attention to the work of Ransom, who demonstrated the method of infestation and was able to show that it was quite possible for the presence of larvæ in the lungs to set up a bronchopneumonia. More recently there has appeared a description of some of the more serious results of ascariasis and, although it is based chiefly upon cases seen in the Philippines and in Brazil, there appears no good reason why their counterparts should not be encountered in this country, though possibly less frequently.

Crowell (*Am. Jour. Med. Sci.*, 1920, clix, 380) divides the effects of infestation with the ascaris into four groups: mechanical, infection carrier, bronchopneumonia, and toxic. The mechanical effects are perhaps the most prominent and are due to a certain extent to the predilection of this worm for narrow orifices. They pass through perforations in the alimentary canal, if indeed they do not hasten the actual perforation of a weakened area, crawl into the bile and pancreatic ducts, appear in

the larynx, and lodge in the appendix and in hernias. They have been found to be so numerous in the intestine as to simulate an abdominal tumor and even to produce an intestinal obstruction. They may cause suffocation when located in the larynx. They do not appear to produce an appendicitis, but their ability to carry infection has been amply demonstrated in several cases of multiple abscesses of the liver. At least once these worms appear to have crawled through the suture line after an intestinal operation and to have determined the onset of a fatal peritonitis. The causation of bronchopneumonia by ascaris larvæ has not been shown to be very frequent in man, but it is certainly possible and such cases may not have been recognized. The toxic effects of the infestation are less readily demonstrable. A toxin has been isolated but it is not certain that it causes definite symptoms. Ascariasis has been found in association with hemorrhages of the purpuric type, but it has not been shown that there was any relation between the two.

It is quite probable that we have no very great reason to fear the ascaris as a cause of death in this locality but its powers for evil should be recognized and guarded against when it is present. For instance, a patient harboring this worm should not be subjected to any operation upon the intestines until after a thorough vermifuge treatment, provided of course that the emergency is not too great. The mere presence of the worm should probably be regarded somewhat more seriously than is at present the habit, and its elimination accomplished when possible.

THE BENIGN FORMS OF ACUTE EPIDEMIC MENINGITIS.

AMONG the meningeal states which clinically recall certain forms of acute cerebrospinal meningitis, while their cytological formula approaches them to tuberculous meningitis, a certain number seem to belong to the group of medullary infections. Their clinical etiological characters are in favor of this hypothesis, but the bacteriological proofs remain to be brought forward. These meningeal processes in children have a sudden onset and the patient's pathological antecedents are most often absolutely negative. The temperature goes up quickly to 103° or 104° F., the pulse is rapid, and the patient soon becomes prostrated. There is violent headache throughout the head, or it may be occipital. A sharp persistent pain is often noted in the cervical region. Vomiting occurs, but it is never severe or abundant. Constipation is not stubborn to treatment and can easily be controlled by enemas or purgation. These general phenomena last one or two days and dominate the clinical picture.

At this phase of the disease the diagnosis is not clear; an infectious process is self-evident, but the absence of localization and an incomplete symptomatology cause embarrassment. This state is of short duration, the symptoms become more precise, and then the second phase of the affection is reached. The little patient offers a true hyperesthesia, fearing the slightest sound or touch. Clinical examination reveals typical symptoms; the temperature oscillates around 102° F., the pulse is rapid, as it was at the onset, but it will now be found manifestly unstable; the respiration becomes irregular and the pupils are unequal, sometimes with strabismus. Stiffness of the neck is marked, and the other signs of meningeal reaction are often present, while Kernig's and Brudzinski's signs are more or less distinct. The patellar reflex is often decreased or absent. Given all these signs, the existence of a meningeal reaction is evident.

This clinical picture does not differ from that of the other meningeal reactions. By the sudden onset, the intensity of the reactions, and the rise of temperature it clinically approaches cerebrospinal meningitis, but lumbar puncture usually gives exit to fluid under high tension, while the fluid is clear and contains a large percentage of albumin. Cytologically, it is interesting. Occasionally there are some large mononuclears and polynuclears, but in the vast majority of cases there is invariably a preponderant — sometimes exclusive — lymphocytosis reading as high as 20 to 30, or more. The most minute researches have so far failed to discover any trace of bacteria and guinea-pig inoculation has been negative.

In spite of the alarming symptoms at the onset, as well as of the evident signs of meningitis and an impressive cytological formula, sedation soon takes place; the symptoms retrogress, and the child becomes playful again. Stiffness of the neck may continue for a few days, while examination of the cerebrospinal fluid proves that the meningeal reaction has not entirely disappeared, but all these progressively subside. Convalescence is rapid and recovery is complete. In most cases of benign meningitis the evolution will be as described, but exceptionally, a durable or even fatal paralysis has been known to occur.

JAPANESE HUMAN EXPERIMENTS ON THE CONTAGION OF GRIPPE.

DURING the pandemic in Japan in the winter of 1918-19 fifty-two men submitted themselves voluntarily to experiment. Some of these had recently suffered from the natural disease while the others had escaped infection. Emulsions and filtrates of sputum were injected into the nasopharynx, filtrates of the blood of infected grippe patients were also injected in the same way, and filtrates of infected blood and sputum were injected hypodermically. The subjects who had been ill with the natural disease showed immunity throughout. The others after an incubation of two or three days, developed typical influenza from both emulsion and filtrate of sputum, complaining especially of severe headache, sore throat, and myalgia. The injection of filtrate of blood into the nasopharynx gave the same positive results, while the hypodermic inoculations with both blood and sputum filtrate were likewise positive. For control purposes cultures of pneumococci and strep-

tococci and Pfeiffer's bacilli with numerous other pathogenic germs, when injected into the nasopharynx, gave results absolutely negative, apparently showing that none of these germs can cause the disease even in mixed cultures. The Japanese experiments, unlike some performed in Europe and America, show that the blood in grippe may be infectious, the contrary having been inferred among us. The products in these experiments came from 43 influenza patients. The question of infection of the blood is important for as a result of the negative experiments it had been decided that the general blood state, save in the terminal stage of fatal cases, was a toxemia and not a sepsis. According to the Japanese results it is a sepsis the cause of which must be an unknown filtrable virus.

Alimentary Anaphylaxis from Pancreatic Insufficiency.

One of the best known of the food anaphylaxes has to do with egg albumin. This type comprises various clinical forms and degrees of severity, ranging from simple diarrhea and urticaria on the one hand to grave and lethal forms of edema at the other extreme, as in angio-neurotic edema of the glottis. The part played in these cases by the digestive tube has never been entirely clear. Nathan in *Le Bulletin Médical* for January 21, 1924, xxxiv, 4, asks whether we should look upon the digestive enzymes as normally our anti-anaphylactic defense forces. If this be the case anaphylaxis would mean enzyme insufficiency and the problem would be simplified. This matter has recently been put to the experimental test by Lesné and Dreyfus. Egg albumin was first treated with pepsin and then injected into a sensibilized animal and anaphylaxis was produced as usual. Pancreatin was then substituted for pepsin and anaphylaxis was absent. Here is the simple solution of a most difficult problem. Pancreatin transforms anaphylactic to non-anaphylactic proteins. An eight-year-old boy had egg anaphylaxis to such an extent that any dish which contained egg caused abundant fetid diarrhea, urticaria and other eruptions, and for years his parents had been compelled to exert the greatest care in feeding him. The child was healthy and normal, presenting only a little meteorism, but analysis of the feces showed that pancreatic insufficiency existed, the stools containing undigested fat and muscle. Pancreatic extract was now exhibited, 40 cg. daily, and at the same time egg albumin was cautiously added to the diet. Tolerance did not, however, develop for when the pancreatic extract was intermitted anaphylaxis reappeared. An exactly similar case has been recorded by Lesné.

Malta Fever in Spain.

According to an abstract from the *Extramadura Medica* published in *La Medicina Ibera* for December 20, 1919, ix, 11, Malta fever as seen in Badajos differs somewhat from textbook accounts. It is an error to accuse only the goat, which may be the chief or sole cause in Malta, for in other countries the sheep, cow, horse, dog, and hare are known to carry the germ. The employes who handle any of these animals may carry the infection on their hands. Four forms are known—ambulatory, intermittent, undulant, and malignant. But three actual patients are mentioned by the reporter in connection with receiving serotherapy. The treatment exerted a specific control over the affection but the degree was not startling. The effects may be apparent only after some patience and the victims are apt to object to the serum injections. This abstract is followed by another from the *Archivos Españoles de Pediatria* devoted to Malta fever in children. Only the milk of infected goats is mentioned under causation along with the breast milk of infected mothers. Some authors are a little sceptical of serodiagnosis by agglutination although with the technique laid down by Finzi it would seem to be beyond cavil. The author, Aguilar Jordan, states that serums and vaccines have alike generally failed at his hands but he has not renounced them, as judging from other affections this negative result may become in time positive. In certain cases some benefit is apparent. In uncomplicated cases arsenic appears to be of service and may be added to vaccine treatment. A third remedy is adrenalin when indicated by evidences of hypoadrenia.

News of the Week.

Caduceus Post of the American Legion.—The Caduceus Post of the American Legion was formed on April 6 by an amalgamation of the Medical Department Post of New York and the Harry D. Gill Post. The great majority of the members are physicians. It is hoped to have a large post of physicians who will be able to make their influence felt in the Legion and to look out for the interests of the medical profession in general, including the Medical Corps of the Army and Navy. All physicians desiring to join the Caduceus Post, either as regular or associate members (the latter class for those who are active members of other posts) should communicate with the Secretary, Dr. Samuel Bradbury, 116 East 63d St., New York City. The following officers have been elected: *President*, Dr. Howard Fox; *First Vice-President*, Dr. Harlow Brooks; *Second Vice-President*, Dr. George E. Maurer; *Third Vice-President*, Dr. Graeme M. Hammond; *Secretary*, Dr. Samuel Bradbury; *Treasurer*, Dr. William P. Cunningham; *County Delegates*, Drs. Harlow Brooks and Chas. J. Imperatori; *Members of the Executive Committee*, Drs. Wiley E. Woodbury, Samuel Lloyd, Russell L. Cecil, and Hector J. MacNeile, and Messrs. Chas. H. Rose and Paul M. Wood.

A Phi Delta Epsilon Banquet in Boston.—A banquet and initiation of the Phi Delta Epsilon Medical Fraternity, Boston, Mass., was held at Hotel Thorndike, Saturday evening, April 10. Representatives from the New York and the Philadelphia Chapters were entertained. Sunday afternoon Chapters Rho and Alpha-Theta, of Harvard and Tufts Medical Colleges, respectively, held an interfraternity smoker at Hotel Copley Square. After a sight-seeing trip through the city the guests departed for a tour among the Western Chapters.

Shortage of Doctors in Bay State.—Dr. Walter

P. Bowers, Secretary of the Massachusetts State Board of Registration in Medicine, is given as authority for the statement that there are seventy-six towns in Massachusetts which are wholly without medical assistance. The war is largely blamed for this state of affairs.

Parker Hill Hospital Head Removed.—Surgeon-General Cummings, of the United States Public Health Service, has announced the removal of Dr. Frank A. Davis, surgeon in charge of the Parker Hill Hospital, Boston, following an investigation of the conduct of the hospital.

Hospital for Babies.—Plans for the $250,000 Anita M. Baldwin Hospital for Babies at Los Angeles, California, are complete and the construction of the first unit of fifty beds is under way. The completed hospital, which will be located near the College of Medicine of the University of Southern California, will contain 250 beds. The directors of the hospital are Dr. Alfred J. Scott, Dr. Gustav Bjorkman, Dr. R. E. Ramsey, Robert A. Anderson and Albert L. Stephens.

Richmond Hospital for Crippled Children.—The Dooley Hospital, in Richmond, Va., just completed at a cost of $65,000, which was intended for contagious diseases but which has not been used for that purpose, is to be given over temporarily to the care and treatment of crippled children until an independent and specially designed institution can be provided for them. The Orthopedic Association of Virginia is interested in making such permanent provision. The Dooley Hospital, endowed by Major James H. Dooley, forms one of the large group of buildings under the control and direction of the Medical College of Virginia.

Anesthetists to Meet.—The eighth annual meeting of the American Association of Anesthetists will be held in New Orleans April 26 and 27, under the presidency of Dr. Albert H. Miller of Providence, R. I. Dr. F. H. McMechan of Avon Lake, Ohio, is secretary.

Physicians Needed for Panama Canal Service.—The United States Civil Service Commission has announced open competitive examinations for physicians in the Panama Canal Service to be held May 5 and July 7. Both men and women are eligible. The entrance salary is $200 a month; promotion may be made to as high as $300, and to higher rates for special positions. Applicants should apply for Form 1312 to the Civil Service Commission, Washington, D. C., or to the secretary of the local United States Civil Service Board.

A "Batty" Story.—According to press reports, a physician living in San Antonio, Texas, has invented and satisfactorily demonstrated the effectiveness of a "Malarial-Eradicating-Guano-Producing Bat-Roost," which has been officially adopted by the city of San Antonio. Having observed that bats subsist chiefly on mosquitos, Dr. Campbell conceived the idea of constructing a roost for bats, to be used in mosquito infested districts. The Texas legislature has taken official cognizance of the invention and has passed a law making it a misdemeanor for anyone to kill a bat in that State. A fine of from five to ten dollars is provided for each bat destroyed. Incidentally, mention is made of the commercial value of the refuse from the bat roosts. It is estimated that five hundred thousand bats will produce about twenty tons of guano annually, which he claims could be sold for one hundred dollars per ton. The principal ingredients in bat guano are ammonia and phosphoric acid. The fertilizer produced by bats is said to be pronounced by experts second to none for productivity.

Charitable Bequests.—By the will of the late Daniel G. Carroll of New York City, the bequests of $100,000 were provided for each of the following institutions: The R. C. Orphan Asylum Society of Brooklyn; the New York Catholic Protectory at Van Nest, Bronx, and St. Vincent's Hospital, New York City. The Cancer Hospital in Cherry Street, New York City, and the Industrial Home for the Blind in Brooklyn, each received $25,000, and the Brooklyn Home for Consumptives was left $20,000.

By the will of the late Catherine A. Delk of Philadelphia bequests are made as follows: Home for Incurables, $1,000; Home for Consumptives at Chestnut Hill, $1,000.

Dr. G. Kirby Collier, formerly Assistant Medical Superintendent of the Craig Colony for Epileptics at Sonyea, N. Y., has removed his office to 525 Lake Avenue, Rochester, N. Y.

Medical Interne Needed.—The United States Civil Service Commission announces an open competitive examination for medical interne. Vacancies in Saint Elizabeths Hospital, Washington, D. C., at $1,200 a year and maintenance, and vacancies in positions requiring similar qualifications, at this or higher or lower salaries, will be filled from this examination, unless it is found in the interest of the service to fill any vacancy by reinstatement, transfer, or promotion. Appointees whose services are satisfactory may be allowed the temporary increase granted by Congress of $20 a month. The positions are tenable for one year. During the year, however, a postgraduate course in mental and neurological diagnostic methods is given, an examination is held, and promotions to the next grade, junior assistant physician, are made. Beyond this there is regular advancement for employees whose services are satisfactory. Saint Elizabeths Hospital has over 3000 patients and about 800 employees to care for. In addition to the general medical practice offered, the scientific opportunities in neurology and psychiatry are unsurpassed. Both men and women, if qualified, may enter this examination, but appointing officers have the legal right to specify the sex desired in requesting certification of eligibles. On account of the needs of the service papers will be rated promptly and certification made as the needs of the service require. In the absence of further notice applications for this examination will be received by the Commission at Washington, D. C., until the hour of closing business on July 1, 1920. If sufficient eligibles are obtained the receipt of applications may be closed before that date. Applicants should apply for Form 1312, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C., or to the Secretary of the local United States Civil Service Board.

Obituary Notes.—Dr. GEORGE S. DARE of Rising Sun, Md., died March 25, at the age of seventy-six. He was graduated from Jefferson Medical College, Philadelphia, in 1866.

Dr. Nicholas C. Trout died of diabetes mellitus, at Fairfield, Pa., on March 24 at the age of fifty-five years. He was graduated from Jefferson Medical College in the class of 1896. He was a member of the Adams County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. Vallindingham Bodey of Dayton, Ohio, died March 23, at the age of fifty-five. He was graduated from Starling Medical College, Columbus, in 1895.

Dr. Samuel Doty Risly of Philadelphia, died April 1, at the age of seventy-five. He was graduated from the University of Pennsylvania School of Medicine, Philadelphia, in 1870, specializing in ophthalmology. He was a member of the American Medical Association, the Section on Ophthalmology of the College of Physicians, and of the Wills Hospital Ophthalmic Society, Philadelphia.

Dr. William Martin, Medical Inspector of the United States Navy, retired, of San Francisco, died April 1, at the age of seventy-one. He was graduated from Tulane University School of Medicine, New Orleans, La., in 1874.

Dr. Robert Elliott Clarke, at one time medical adviser to Queen Victoria, died March 27, at the Matteawan Hospital, where he had been a patient for two years. He was sixty-six years of age.

Dr. Charles Dudley Prescott of New Bedford, Mass., died March 26, at the age of seventy-five. He was graduated from Darmouth Medical School in 1867. For many years Dr. Prescott was attending physician to St. Luke's Hospital, and he was a member of the state and local medical societies.

Dr. Ovila C. Gelineau of Indian Orchard, Mass., died March 27. He was graduated from Baltimore Medical College in 1894.

Dr. Joab Stowell, Jr., of Amherst, Mass., died suddenly March 27, at the age of fifty-eight. He was graduated from the University of Minnesota Medical School, Minneapolis, in 1890. He was a member of the state and local medical societies.

Dr. Edgar C. Loehr of Noblesville, Ind., died recently following a stroke of paralysis which he had suffered several weeks previously while attending the theater in Indianapolis. He was 70 years of age, and was graduated from the Medical College of Ohio, Cincinnati, in 1871.

Dr. John T. Blank, for twenty years a practising physician at Elk City, Kansas, was instantly killed on March 30, when his car was struck by a passenger train. Dr. Blank was graduated from the Electic Medical College of Cincinnati in 1890.

Dr. George P. Cooley of New Britain, Conn., the oldest practising physician in the State, died April 3, at the age of 91. He was graduated from the Pennsylvania Medical University, Philadelphia, in 1862.

Correspondence.

OUR LONDON LETTER

(From Our Own Correspondent.)

London, April 2, 1920.

Heart Disease and Its Treatment.—It does not happen often that a dissertation on medical science is given in the British House of Commons. This is, however, what happened the other day, on March 19, a bill was brought to the House to prevent the vivisection of dogs and in the discussion which ensued Capt. W. E. Elliot, a medical man who is also an M.P., told his fellow members of the results and hoped for results of experiments on animals. The speaker began by saying that it was not a bill to prevent giving pain to dogs. It was simply a pettifogging bill to obstruct as far as possible the progress of medical science. He went on to point out that owing to experiments on dogs the discovery of what heart disease really is, was well on the way and that the experiments already done were carried out on dogs under complete anesthesia, the dogs were killed before they recovered from the experiment, and these experiments would have been completely stopped by the passage of the bill which was before the House of Commons last March. According to Capt. Elliot these experiments have proved that the heart beat starts by an impulse beginning at the top of the heart and passes down in a cerain sort of current through the muscle. In heart disease the wires are faulty and the circuit is bad, in fact, disease is due to the break up of this impulse passing through the heart from the top to the bottom and that gives a direct line how to successfully treat this condition. The speaker said that all these things had been found out very largely during the past twelve months, and very largely because of the rejection of the bill by the House last March. Capt. Elliot declared that when really definite results of this kind had been obtained, the House would be taking a step of the gravest responsibility to stop such experiments, to squash the results of nine years of experiment, scrap it, and throw it into the waste-paper basket and cause another step to be made. Lastly, the speaker drew attention to the fact that the Medical Research Committee which was set up by the House of Commons published a very strong and an absolutely unanimous recommendation about the dogs' bill. They consider that the passage of the dogs' protection bill, designed to prevent experiments on dogs, would mean serious and in some instances fatal hindrance to research work.

Surgical Treatment of Gastric and Duodenal Ulcers.—While it is freely allowed that the correct, indeed, the only hopeful treatment of chronic gastric and duodenal ulcers is by operation, it must not be forgotten that several points must be decided before operative measures are undertaken and then the question arises what form of operation shall be done. Sir Berkely Moynihan and his followers point out that gastric ulcer is not nearly so common as the duodenal variety and the reason why it is so frequently operated for is because the diagnosis has been inaccurate. They state that clinical diagnosis is wholly unreliable and that the only certain way of finding out the exact situation of the ulcer, is by an exploratory operation or by the *x*-rays. Employed by an expert, the *x*-rays as means of diagnosis are quite sufficient in the great majority of cases. As for the form of operation for gastric ulcer Moynihan and his school say that partial gastrotomy is the best. They

give several reasons for this statement, perhaps the chief of which is that it precludes the occurrence of carcinoma. At a meeting of the Section of Surgery of the Royal Society of Medicine on March 3, last, a discussion of the remote effects of the surgical treatment of gastric and duodenal ulcers took place. Mr. Herbert G. Paterson opened the discussion, dealing with the remote effects of the operation of gastrojejunostomy and concluded as a result of the experience and deductions therefrom that gastrojejunostomy was not a mechanical but a physiological operation, and its action was to enable nature to counteract hyperacidity and neutralize the effects of hypersecretion. With regard to the effects of the operation on metabolism, a series of experiments showed that the operation did not appreciably diminish the proportion of nitrogen or fat absorbed from the food. Therefore we were justified in concluding, by both clinical and pathological evidence, that the operation of gastrojejunostomy did not appreciably interfere with the metabolism of the human body, and was compatible with the enjoyment of perfect health. Mr. Paterson favors the operation of gastrojejunostomy. Mr. James Sherren thought that as a rule gastrojejunostomy correctly done was quite effective but there were instances in which he employed partial gastrectomy. Malignant disease of the stomach might occur at remote periods after treatment of chronic gastric ulcer by gastrojejunostomy alone. In 3 per cent of chronic ulcers of the stomach which he had removed at operation, the naked eye diagnosis being simple and there being no evidence or suspicion of malignancy, carcinoma starting at one edge was discovered on microscopic examination. It may be pointed out that there is no standardization of operative treatment for gastric and duodenal ulcers. In Great Britain there is a general concensus of opinion among surgeons that gastrojejunostomy is the operation of choice for duodenal ulcers, but there is a wide difference of opinion with regard to its value in gastric ulcer. A considerable number of surgeons here are inclining to Moynihan's views that partial gastrectomy is the best form of operation for chronic gastric ulcer.

Dinner to Sir John MacAlister at the Connaught Rooms.—On Thursday evening, March 18, the Royal Society of Medicine which he created, gave a dinner to Sir John MacAlister, its secretary, to congratulate him on his recently conferred knighthood. Sir John MacAlister is well known, and thoroughly esteemed and appreciated by the numerous American army medical officers who when in London during the war were given the freedom of the Royal Society of Medicine and largely for whose hehalf, the Fellowship of Medicine and Post Graduate Association was founded. But there is no need for anyone to praise Sir John MacAlister to those Americans who have met him or known him and it is sufficient to say that their good feeling is thoroughly appreciated. It is an open secret that the secretary of the Royal Society of Medicine is a great admirer of American medical men and that it was a pleasure to him to meet them and to observe their keenness in all that concerned the pursuit of medical knowledge. At the dinner to Sir John there was a very large and representatvie gathering which included well-known members of every branch of the medical profession and of every town in the country. Sir Humphrey Rolleston, president of the society, was in the chair. The keynote of the meeting was struck by Sir Arbuthnot Lane who pointed to the material results of Sir John's labors. According to the audited accounts of the society in 1887 the balance of assets standing to credit was £3,040. In the last audited balance sheet the balance of assets as audited by chartered accountants stood at £75,000. But in that account the value of the society's new house was merely put down at the actual cost of site and building. Since then the lease has been extended from 80 years to 999 years. The value of this asset alone must therefore be at least £100,000. The real difference between 1887 and 1920 was over £120,000. It is no exaggeration to say that Sir John MacAlister has placed the Royal Society of Medicine in the high position it occupies at the present time. The Royal Society of Medicine came into being with the object of uniting a large number of smaller societies and thus to give more weighty expression to the medical opinion of the country. It goes without saying that the work of amalgamation was extremely difficult and one which called for the employment of a great deal of tact. Sir John MacAlister was equal to every occasion and succeeded in all his efforts. His reward has consisted in seeing the aim of his life accomplished, the Royal Society of Medicine established on a firm foundation and its work enlarged in every direction. During the war its house became the meeting place of medical men of all nations, and especially of Americans and Canadians, and as is known to the readers of these letters has been made the headquarters of the Fellowship of Medicine and Post Graduate Association. There is no doubt that Sir John's many friends in America will be delighted to learn of the well deserved honors that have been paid him and will wish him many years of good health in which to enjoy them.

The Cooperation of Sir Robert Morant and Sir George Newman.—Sir Robert Morant who died the other day and who was responsible for the working of the British insurance bill and largely responsible for the initiation and establishment of the Ministry of Health coordinated with his complimentary personality Sir George Newman, chief medical adviser of the Ministry of Health some years ago. In fact, they first met in 1907 when the then Dr. George Newman and Mr. Robert Morant were both members of the Board of Education. They had visions then of a Ministry of Health, which mainly by their exertions has come into being. Sir George Newman's appreciation of his friend and coworker in the *British Medical Journal*, March 20 last, is interesting and somewhat pathetic.

Triennial Meeting of la Société Internationale de Chirurgie in Paris.—The fifth triennial congress of the International Society of Surgery will be held in Paris instead of in Brussels, July

19 to 23, 1920. The delegates of Great Britain and Ireland to the General Committee are Sir William Macewen, C.B., Sir D'Arcy Power, R.B.E., and Mr. Paul Bush, C.M.G., C. B. E. The International Committee has drawn up the following provisional program: Cardiovascular Surgery: Surgery of the Heart, M. Tuffier, Paris; Surgery of the Great Vessels, Mr Sencert, Strasbourg; Transfusion of Blood, M. Tembraux, Montpellier; Surgery of the Heart and the Great Vessels, M. Alessandri, Rome. Surgical Radiology: The Treatment of Tumors by X-rays and Radium, M. Regaud, Paris, and Dr. U. S. Finzi, London. Surgical Hematology: Analysis of the Blood and Biological Reactions in Surgical Affections, M. M. A. Depage and Goovaerts, Brussels. Fractures of the Thigh, M. Ratel, Lyons, and Major Maurice Sinclair, Fairport; Prophylaxis and Treatment of Tetanus, M. Donati, Modena, and Mr. Cummins, London.

At the close of the congress a week's tour will be made of the battlefields in France and Flanders. The ticket for the tour is 815 francs, which includes railway and automobile transport, together with the service of guides. The meeting will be under the presidency of Professor W. W. Keen, of Philadelphia.

A Notable Work on Oto-Rhino-Laryngology.—Dr. Georges Laurens is a well-known name to medical men everywhere as an authority on diseases of the nose, ear and throat and their treatment. To those who know French his text-book dealing with oto-rhino-laryngology is familiar and is perhaps acknowledged to be in many ways the best published. It is unique in character, for it tells with the most minute and most meticulous adherence to details how to treat a large variety of nose and throat cases. It is a book indeed which describes "what to do" and "what not to do" in each particular case. It is a manual especially adapted for the use of the general practitioner and for students who do not live near large centers of population and in consequence are out of touch with specialists, whose knowledge is mainly theoretical but who are anxious to know something of the technique of this branch of medicine.

A feature of the book is its numerous illustrations and diagrams which serve to elucidate the text and to enable the practitioner to gain a very good idea of how to put the instructions laid down to practical use. The ground covered is remarkably extensive and by following the precepts of the book, the general practitioner should be able to give expert advice to those suffering from diseases or affections of nose, throat or ears, tell them when to seek the advice of a specialist and not to have always to say, "Oh, I know nothing about that branch of medicine." The book throughout is written and expressed in the clear, logical style distinctive of the French. Lauren's work has been translated recently into English by Mr. Clayton Fox, a well-known London laryngologist. The translation is really excellent. It is faithful insomuch as it succeeds in not only converting the French into good readable English, but what is more difficult by far clearly conveys the meaning of the French phraseology. It may be said that Mr. Fox has done English-speaking medical men a good turn by rendering available to them such a work as that of Laurens. The English translation is published by John Wright & Sons, Ltd., of Bristol.

CONCERNING MASSEURS AND MASSAGE.

To the Editor of the Medical Record:

Sir:—For an unsuspecting mechanotherapeutist who arrives in New York to exercise his profession there is a strange welcome in store; all the more strange if he happens to be a Swedish Medical Gymnast, coming straight from Sweden, where he has been fostered to regard himself and his profession as quite respectable. He has heard of the fifty-story buildings in this strange fantastic city of New York, and enjoys the thrill of being thrown up to quite remarkable altitudes in really most excellent elevators—in itself a mechanical treat—(ment)—only to find in the next moment that there are also depths, unsuspected abysses of humiliation at the bottom of which he begins to wonder what sort and manner of a person he might be, after all. Is it possible that he is only just emerging from a fool's paradise into hard reality, that in choosing what was considered a decent profession he lowered himself into the lowest strata of social life, with only one step to its pariahs.

Says the Cosby's Code of Ordinances of the City of New York, 1919, Chapter 14—*Licenses*:

"Article I, Sec. 1. In addition to the business, places, trades, occupations and things required to be licensed by statute or by other chapters of this code, the following must be duly licensed as herein provided, namely: Bowling Alleys, Dealers in Second-Hand Articles, Handorgans, Itinerant Musicians, Peddlers, Hawkers, and Vendors, Shooting Galleries, Street Musicians, Junk Dealers, Dirt Carts, and Masseurs."

That is the first slap in the face, but while still blushing under the humiliation that the City of New York affords the newcomer by placing him in such charming company his breath fairly fails him when he reads:

"Sec. 2. No person shall be licensed under any provision of this chapter or of Chapter III of this ordinance, except a citizen of the United States or one who has regularly declared his intention to become a citizen."

Now, sir, that is a tall order to ask a young man, at least a Swede, to swear that he intends to renounce forever all allegiance and fidelity to his king and country—*so help him God*—before he has ever had time to find a roof over his head. I put it to you that that is more than has ever been demanded of any American citizen in any other country on earth.

Why does he not stay at home, somebody suggests. Exactly, and why do not Americans stay at home? Why all this sentimentality about a League of Nations, International Brotherhood, one nation needing another, the blind helping the lame, the Americans doing dentistry for the Arabs; the Danes pastry for the Americans?

American citizens may actually have requested him to come here to assist them. He had still the choice of staying at home. Maybe! One thing is

certain; if he be a Swedish Medical Gymnast, seeing what he has been led into there will appear to him no choice at all but to go back. But there is the ocean and even if he has the means and the chance of obtaining a berth, maybe he has a strong aversion for sea voyages. So he is more or less compelled to stay and face the music. Cheerfully.

And, if he be married, just hear him cautioning his wife and children: "Great country this; plenty of money over here, at least so they say. Haven't seen any as yet. But, as for social position, the country is so tremendous that you will only rank somewhere between a peddler and a dirt-cart."

Once in Cairo I happened to mention to an American diplomat of the arrival at Alexandria of Count Hamilton, the scion of one of the oldest families in Sweden, officer in one of the king's crack regiments and a medical gymnast.

"Good Heavens!" exclaimed this shocked democrat. "You don't want to be massaged by a count; he must be badly down on his heels to have taken up such a profession." "Not more," I ventured to say, "than Baron Cederström, who married Patti." "But he was an aviator." "Yes, but first and last a medical gymnast."

I do not suggest that masseurs should be titled. On the contrary, I sincerely believe that the institution which has brought so many of our Swedish officers into the profession—the Royal Central Institute of Gymnastics, in Stockholm—no longer possesses its *raison d'être*. True, it has given to the profession a number of well-bred, socially well versed representative young fellows who, commandeered to the institute for military purposes have availed themselves of its medical course, and who later naturally enough have given in to the temptation of the more interesting field of therapeutics, and while remaining in the reserve of the army, have gone abroad as medical gymnasts.

But the combination of medical and pedagogical gymnastics must needs be considered a disadvantage to both, from the point of view of practical science. No, I do not suggest that masseurs should be titled or that the fact that so many Swedish masseurs are titled has in any way added to the efficiency of the Swedish School of Massage. Aristocracy has to-day, by far, not the same high rate of exchange in Europe as evidently it has on this side. But, for that very reason—speaking of the social status of the masseur in this country, I have mentioned these names merely to give a stronger relief to the absurdities with which this article concerns itself.

Let us return to them! The greatest of them all is the Food Handlers' Card.

To obtain a license as a massage operator the newcomer must produce a food handlers' card—that is, a card upon which a medical man states that the applicant is free from consumption, syphilis, and objectionable skin diseases in general; is of suitable height and weight, in short, is fit to handle—meat, and this is where the thing becomes positively funny. Evidently, the good New Yorkers are considered by the municipal authorities as so many fillets of beef, and nothing more. But better not laugh too soon. The matter is exceedingly grave. The applicant must produce affidavits from five citizens, duly attested by a notary public, stating that he is to them known as an honest individual. Which, of course, the police officer before whom he has to pass finds absolutely incredible. Can any honest man be a masseur? With these affidavits in front of him, the Mighty One will look at his prey searchingly and thus interrogate: "Ever been in prison?" "No." Ever been convicted of crime?" "No." And then, leaning forward, and with a look that could make any honest youth feel like a criminal: "Sure you have never committed a crime?" And when the answer is still in the negative, he is evidently disappointed.

And, if after weeks of waiting, the applicant obtains a license he is at the absolute command of the police—a chartered libertine. Ah, but there is a reason for all that, I am told. No, there is no reason. It is unreasonable! It is unpardonably clumsy—"groft," to use a Swedish word. The fact that in this country crimes and indecencies have been, and are possibly still, committed under cover of "massage," constitutes no reason for discrediting so important a factor of healing as massage, or its duly qualified operators as a class.

The fact that in Ancient Greece the physician was a beggar who largely relied on charity for a living does not necessarily entitle even a Greek to look upon an American physician of to-day as a mendicant. Not even the fact that in this city of New York members of the medical profession are caught performing illegal operations makes it a valid reason for anyone to denounce that profession as disreputable. Black sheep *will* crop up in every camp, and I guess the massage fraud is the clumsiest and easiest to detect. And so there are deplorable exceptions also among Swedish masseurs and masseuses, but on the whole, and as a class, the medical gymnasts, as representing the Swedish school of mechanotherapy, have brought home to the world the importance and the undeniable value of massage and have kept aloof from the mire and filth which they found within their profession abroad.

This is, I think, freely admitted by the medical profession of most countries to-day.

If, then, medical men in this country realize and appreciate the value of massage as a factor of healing, and masseurs as a necessary auxiliary in their work, why is it that they on the whole seem so indifferent as to what really happens to both massage and masseurs? Why is it that while tolerating the mysterious development of a Turkish bath attendant into a "masseur," they permit the properly qualified men to be exposed to the humiliating indignities of a nonsensical law?

And why is it that certain mechanotherapeutists not only are exempt from that law, but even suffered to style themselves "doctors"—merely because they camouflage their manipulations with strange and resounding names. (Only this morning I received from a school of "chiropractice" an offer to turn me into a "doctor" in far less time than it took me to graduate as a medical gymnast. "A wonderful future" I am promised. No doubt!)

Surely the Academy of Medicine, or some such body, could bring some kind of cosmos into this chaotic state of affairs.

4. Renal Function in Vascular Hypertension.—James P. O'Hare emphasizes the importance of differentiating vascular hypertension from chronic nephritis. He considers it so easy that no one should be excused for error except in the rare borderline case. The vascular hypertension patient can be recognized clinically by his characteristic healthy appearance, by his lack of pure renal symptoms, and by routine physical and laboratory examinations. He can be recognized more surely and more readily by the tests of renal function. Twenty-five cases of vascular hypertension are tabulated to show how readily the functional tests in common use establish the diagnosis. The uranalysis is included because in these cases it resembles closely that of the patient with nephritis, and yet it may show certain elements which would lead one to suspect the true diagnosis. The writer summarizes the table of cases by stating that in vascular hypertension the specific gravity of the urine shows no loss of power of concentration, as in chronic nephritis; albumin and casts appear in the same quantities in both diseases; the functional tests show but little renal impairment; a markedly increased night volume of urine indicates a possible renal death.

7. Narcotic Drugs and State Legislation.—A. D. Greenfield, discussing the problem of alcohol from the legal point of view, holds that in order to determine what is needed in State legislation relative to narcotic drugs it is necessary to consider, first, the facts with regard to the use and abuse of these drugs, and, second, the scope and effect of Federal legislation. The general nature of the legislation demanded will naturally depend on a determination of the conditions requiring remedy; and the particular scope and purpose of State legislation will depend on how far and how effectively these conditions are already dealt with by the Federal law. Every State law should contain a provision calculated to prevent the abuse of the physician's privilege. Such provision should be drawn with the greatest care not to interfere with medical treatment of cases other than drug addiction. The simplest way of covering this point is by forbidding physicians to prescribe or dispense these drugs except when required in the *bona fide* treatment of a disease or condition other than drug addiction, permitting personal administration, however, in any case. To forbid personal administration would interfere with legitimate institutional treatment of addicts by the reduction method. The practical effect of such a law as this, if adopted by all States and strictly enforced, would be to force addicts to be cured; and as a corollary to it the States or municipalities ought to make provision for institutional treatment of their addicts. With respect to many features that would be proper subjects for State legislation, uniformity would be most desirable; in others it probably would not be necessary or practicable. The judicious drafting of proposed legislation which would be suitable for adoption by all the States could best be accomplished, the writer believes, by a committee, whose labors should be based on a careful study of all existing State legislation on the subject.

7. The Treatment of Injuries to Athletes. Harry Eaton Stewart.

1. Basal Metabolism Determinations in General Internal Diagnosis.—G. W. McCaskey holds that the routine determinations of basal metabolism are applicable to the following groups of cases: 1. In all cases of definite goiter, and especially if associated with health disturbances, to ascertain the degree, if any, of its toxicity. 2. In a large group of cases, either with or without goiter, with symptoms resembling, either closely or remotely, those of thyrotoxicosis. He considers that the procedure has passed the experimental stage and he has given it a place in his diagnostic armamentarium along with the roentgen ray, the electrocardiograph, serology, calorimetry, clinical chemistry, etc., to be used as occasion requires. While its precise limitations and scope will, of course, be more clearly defined with larger experience, and especially with a fuller knowledge of the endocrinopathies, the attainment of which will be greatly stimulated by its use, the information which it gives in certain cases appears to be indispensable in the writer's experience, and cannot be otherwise accurately obtained. He reports in detail the histories of eight patients.

6. The Thézac-Porsmeur Method of Sun Treatment.—Robert L. Lovett reports a series of twelve cases of chronic suppuration in the orthopedic service of the Children's Hospital, Boston, which were treated by heliotherapy applied by means of a double convex lens with a diameter of twelve inches and a focal length of seventy-two inches. At the focal point, of course, the heat is very great, as it would be in any lens used as a burning glass, and in general the patient should be placed at a point where the sun's rays form a circle of from three to five inches in diameter. As the patient is moved farther away from the lens the heat increases, and as the patient is moved nearer to the lens the heat diminishes. The degree of activity to which it is desirable to submit the wound can be regulated by carrying the lens nearer the patient or farther away. The duration of the treatment should lengthen progressively. The first treatment should last for five minutes, increasing at the rate of five minutes a day up to thirty minutes. The effect of the treatment on suppurating wounds was perfectly definite: 1. The discharge immediately increased and then diminished; 2. pale granulations took on a healthier color, and 3, sensitiveness diminished. The cases treated were selected because of the severity of the suppurating wounds. The value of the treatment would seem to have been demonstrated in cases of chronic suppuration from tuberculosis, syphilis, and chronic osteomyelitis.

8. Military Hygiene in Olden Time. Sir John Goodwin.

1. Surgical Aspect of Dysentery.—Zachary Cope states that surgical complications are not common in dysentery; yet when the disease is very prevalent many occasions arise calling for the opinion of the surgeon, and not infrequently needing his operative interference. The surgeon may meet with dysentery in three ways:

1. Dysentery may develop as a complication of surgical conditions; 2. various surgical conditions may be simulated by dysentery; 3. complications needing the surgeon may arise in the course of dysentery. The surgical complications of dysentery may be classified as those due to local processes in the intestine; those following on the remote effects of the organism or its toxines; associated surgical conditions. Under the first category are included: 1. Perforation of colon causing general peritonitis, pericolitis, or pericolic abscess. 2. Acute edematous localized colitis—for example, typhlitis. 3. Dysenteric appendicitis. 4. Extensive sloughing, the colon pus sac. 5. Cicatrization and stricture of the colon or rectum. 6. Perinephric abscess. 7. Periproctitis. The associated lesions are parotitis, boils and abscesses, thrombosis (gangrene of foot, pseudo-elephantiasis of leg).

3. The Life-History of the First Case of Myxoedema Treated by Thyroid Effect.—Professor George R. Murray reviews the history of the first case of myxedema successfully treated by thyroid extract, the results obtained in this case not only affording definite proof that the thyroid gland produced an internal secretion, but showed that the thyroid insufficiency of myxedema in man could be made good by maintaining an adequate supply of thyroidal hormones from an external source. He recalls the publication of the report, in 1888, of the special committee which was appointed by the Clinical Society (London) in 1883 to investigate the relation of myxedema and allied conditions to the thyroid gland. The experimental work of Sir Victor Horsley, which was undertaken at the request of this committee, first proved that myxedema, and cachexia strumipriva were due to loss of function of the thyroid gland. Although at that time it had not been proved that this function was to provide an internal secretion, he suggested that grafting a portion of healthy thyroid gland would be a rational method of treating these maladies. The striking improvement which followed the adoption of this suggestion in the case of Bettencourt and Serrano led Murray to suggest and carry out the treatment of myxedema by thyroid extract in the case whose life history he now records as an example of the value of observation of individual cases over long periods of time in the elucidation of certain problems in medicine. This patient, a woman of forty-six when the treatment was begun, in 1891, lived until early in 1919, when she died at the age of seventy-four. By the regular and continued use of thyroid extract she was enabled to live in good health for over twenty-eight years after she had reached an advanced stage of myxedema. During this period she consumed over nine quarts of liquid thyroid extract or its equivalent, prepared from the thyroid glands of more than 870 sheep.

4. The Use of Antistreptococcic Serum in Quinsy.—Noel C. Forsyth reports a series of ten cases of quinsy in which the following routine was adopted: Serum (10 c.c. was injected at once; if there was any doubt of diphtheria, 2000 units of antidiphtherial serum were added. The injection was made in the thigh, hypodermically. The usual initial purge was given, and thymol, carbolic lotion, and hydrogen peroxide were used for washing out and swabbing the mouth and throat. The most definite result obtained with this treatment was the relief of pain, which was appreciably relieved in from six to twelve hours. The more or less acute pain when swallowing was eased some hours after that, but within a definite time before the abscess ruptured. In no case was incision of the abscess required by reason of the severity of the symptoms, and in all but one case pus was discharging from the abscess on the fourth day of the illness, and in this one on the fifth day. A polyvalent antistreptococcic serum was used.

Hygiea.

January 31, 1920, lxxxii, 2.

Diagnosis of Basedow's Disease.—Troell first refers to the conventional triad of symptoms—struma, tachycardia, and exophthalmus. He next enumerates other evidences which are due presumably to the disturbance of thyroid activity, as emaciation in the presence of normal appetite and the neuropathic symptoms, notably those of motor activity, which may be numerous and varied. He quotes extensively from the writings of Goetsch of Johns Hopkins, who makes use of provocative adrenalin injections in diagnosis. This method he has tested on his own material. In one patient in whom the disease has existed for many years the injection of adrenalin raised the pulse frequency from 106 to 130 and the blood pressure from 145 to 175. Hemistrumectomy was then performed, after which the increases were as follows: pulse 80 to 88, blood pressure 130 to 135. In another case with severe type of disease, but relatively low pulse and blood pressure, the provocative injection caused an increase of pulse from 98 to 128 and of blood pressure from 145 to 228. But after ligation and subsequent strumectomy the adrenalin test was no less positive than before, although patient had rapidly improved and had gained 17 kilograms. The results in general do not appear to show any definite necessary relationship between adrenalin hypersensitiveness and the degree of severity of Graves' disease.

Lumbar Puncture in Wood Alcohol Blindness.—Zethelius mentions the negative results of diaphoresis and potassium iodide in the prevention of blindness during acute methyl alcohol poisoning and states that in three cases treated by himself with lumbar puncture he obtained one good and one fair result. One patient, a syphilitic and alcoholic, drank 50 to 60 c.c. of wood alcohol without apparent ill effect, and for several days be continued to consume this substance. On the fourth day abdominal pain set in, with failure of vision. The Wassermann of the blood and spinal fluid was negative, but the puncture showed that the fluid was under pressure with a positive Nonne. He improved under the puncture and this was repeated several times, with the end result that his vision was left but little impaired—slight retraction of temporal visual field of the right eye.

Le Progrès Médical.

February 28, 1920, xlviii, 9.

Aliments.—Loeper in a lecture on this subject brings out numerous points of interest. One of the most necessary constituents of the body—sodium chloride—can be a menace in disease of the kidney. Despite this drawback it has been termed the "money of exchange" of the organism. But 1.5 daily gms. are necessary, yet many men take in ten-fold that quantity, which is mostly waste, going off by the kidneys. We need potassium badly, but only about 45 cgs. daily. We need calcium, but it absorbs poorly. If we take 1.5 gms. as our daily requirement, only half is absorbed into the tissues, the balance escaping by both urine and feces. The child needs much more in proportion and so can absorb more. We need to ingest phosphorus to the tune of 3.6 gms. of phosphoric acid daily, but at least 2 gms. of this is excess which will go off by the kidneys. Iron in anemia wastes away by the intestine and can be recovered from the villi. The nervous system needs magnesium, the muscles potassium, the tendons sodium, etc., etc. The child utilizes milk much more completely than the adult, and this includes the calcium content. In health cooked foods seem more digestible, but in certain illnesses this rule does not apply, and raw milk, for example, is more nutritious than cooked milk. The utility of raw eggs, raw beef juice, raw fruit juices, in certain ailments is well known, and this leads us naturally to enzymes and vitamines, which products are largely destroyed by cooking and other methods of preparation.

Book Reviews.

La Diatermia como Medio de Tratamiento de los Procesos Ulcerativos de Aparato Digestivo. By Dr. Santiago Carro, Profesor de Vias Digestivas del Instituto Rubio, etc. Madrid: Sucesor de Enrique Teodoro, 1919.

This small pamphlet of thirty pages comprises an account of eight cases of miscellaneous gastric disorders treated with diathermia. Each case is accompanied by chemical analyses and blood counts and in each the diagnosis of ulcer was made, presumably ulcer of very limited extent, the management being largely of the prophylactic type and suitable for suspicion or presumption of ulcer. The theory is that elevation of the temperature of the stomach to 45° C. or thereabout will notably facilitate cicatrization. If there is a tendency to hematemesis the treatment is distinctly contraindicated because of the liability of the current to cause hyperemia.

La Tension Artérielle en Clinique; Sa Mesure, sa Valeur Séméiologique. Par le Docteur L. Gallavardin, Médecin des Hôpitaux de Lyon. Second edition. Paris: Masson et Cie, 1920.

Although the full significance of blood pressure changes is by no means as yet accurately determined, there is nevertheless no question of the value of its indications and the promise its study holds out in the way of diagnosis and especially prognosis. Already, indeed, it has been said that what thermometry is to the diagnosis and prognosis of acute diseases that is sphygmomanometry in chronic diseases.

The first part of this book is devoted to a description of the various forms of apparatus employed in the estimation of systolic and diastolic pressures and their use, but the larger part deals with the clinical and therapeutic study of arterial tension. This part of the work is admirably done, the author being an expert in this branch and speaking with the authority of one with wide experience. The book will repay study by anyone who can read French understandingly, for he will thereby approach the subject from a different angle and will learn the methods and viewpoints of the foreigner, which are not always the same as his own.

The Surgical Clinics of Chicago. Vol. III, No. 3. June, 1919. Pp. 348 with 118 illustrations. Philadelphia and London: W. B. Saunders Co., 1919.

This issue not only contains more than the average number of pages, but the material itself embraces a wide and interesting field, so that not only the general practitioner and occasional operator, but the expert surgeon as well will find much that is well worth reading. Among the most interesting clinics and lectures are: Moodie's article on ancient skull lesions and trephining in prehistoric times; and clinics by Davis on cysts of the urachus, by O'Neill on persistent patent omphalomesenteric duct, by Lounsbury on cases of plastic repair of the heel, by Lespinasse on sterility, by E. L. Moorhead on strictures of the esophagus, by Halstead on diverticula of the esophagus, by Meyer and Moncreiff on volvulus, and Bevan's case of obstruction of the common bile duct.

Anesthésie à la Stovaïne en Chirurgie et en Médecine Vétérinaire. Anesthésie Régionale. Anesthésie Locale. Par Gustave Perol, Médecin-Vétérinaire, Officier du Mérite Agricole, Lauréat de la Société Centrale de Médecine Vétérinaire, etc. Paris: Masson et Cie., 1919.

This small brochure contains 32 pages of text and 6 photographic plates comprising a total of 8 figures. The subject matter is extremely simple—the blocking of the nerves of the four extremities by conduction anesthesia with stovaine solutions. The aim of the author is to call attention to the possibility of regional as opposed to general anesthesia. In addition to the therapeutic possibilities this anesthesia is of value for diagnosis and the same injection may answer for both ends. Local anesthesia receives a short mention, but the text and plates deal chiefly with blocking. For this purpose the author originally used only cocaine but was led later to experiment with the less toxic drugs, and stovaine proved to be the most satisfactory for nerve trunk analgesia.

The Peritoneum. By Arthur E. Hertzler, M.D., F.A.C.S., Surgeon to the Halstead Hospital, Halstead, Kan.; Associate Professor of Surgery, University of Kansas; formerly Professor of Pathology, Experimental Surgery and Gynecology, University Medical College, Kansas City, Mo. Two volumes. Vol. I, Structure and Function in Relation to the Principles of Abdominal Surgery. A contribution from the laboratory of the Halstead Hospital and from the Department of Anatomy of the University of Illinois. Vol. II, Diseases and Their Treatment. St. Louis: C. V. Mosby Co., 1919.

The first volume of this work is devoted to a consideration of the structure and function of the peritoneum in relation to the principles of abdominal surgery. The physiology, histology, development and gross anatomy of the peritoneum occupy about three-fifths of the volume, the remainder covering wound healing, various problems regarding peritoneal adhesions, changes in circulation, pericolic and other membranes, and the inflammatory reaction of the peritoneum. The latter half of the book is particularly rich in material of special interest to the operating surgeon. The futility of using olive oil and other such agents for the prevention of adhesions, and the need for being careful to avoid unnecessary abrading of peritoneal surfaces, are pointed out, also the need for care in making incisions so that peritoneum will be available for the covering of raw surfaces made by dissection or resection of tissues or organs. All these subjects are very well covered; but for the benefit of both students and surgeons, the majority of whom are less well versed in embryology than the author, we would suggest that in the next edition, before discussing in detail the development and gross anatomy of the peritoneum, a chapter be inserted covering these subjects in a concise but clear way, in narrative style and with the least possible digression to take up technical points, so that the anatomic puzzle which the peritoneum presents to the non-expert may be elucidated in a general way and the main facts may not be lost sight of in a maze of detail. The reader will then be better able to follow the text, with its mass of detail, as it now stands, and appreciate the elucidation of the more complex problems of special regions as well as those of the peritoneum as a whole.

The second volume is devoted to the discussion of diseases of the peritoneum and their treatment, and is divided into two parts. Part I is concerned with a very exhaustive discussion of the classification, etiology, pathogenesis, symptomatology, diagnosis, prognosis and cause of death in peritonitis, the treatment of acute peritonitis, and a chapter on operations on the peritoneum. Part II takes up the discussion of peritonitis as found in appendicitis and cholecystitis, also various types of peritonitis such as gonococcic, pneumococcic, puerperal, traumatic, fetal and tuberculous. Finally there are chapters on thrombosis and embolism of the mesenteric vessels, diseases and injuries of the great omentum, and tumors of the peritoneum, this last appealing to the reviewer as giving a remarkably interesting and instructive presentation of that phase of the subject.

Throughout the work, and in the second volume particularly, the relation of the matter under discussion to clinical surgery is kept well to the fore. The author seems somewhat timid at times in his suggestions regarding operative technique, as, for example, in his advice regarding drainage rather than removal of the gall bladder in certain cases; but without doubt the conservative methods suggested are generally advisable except in the hands of the expert surgeon.

In general we would say that this is an excellent work which everywhere shows evidence of painstaking personal research as well as a very comprehensive grasp of the literature. The illustrations are excellent, but the value of many of them would be enhanced by a little elaboration of the underlying legends; while in some, especially those copied from other works, as on page 85, the letters indicating portions of the illustration are not translated in the legend at all. There are many typographical errors, but generally the meaning is clear, one of the exceptions perhaps being in the word "present," line 9, page 740, where *prevent* would seem to be intended. These books will well repay reading and will grace any surgeon's library.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

SECTION ON MEDICINE.

Third Day—Thursday, March 25.

SYMPOSIUM ON GASTROINTESTINAL DISEASE.

Practical Clinical Laboratory Diagnosis in Gastrointestinal Disease.—Dr. HOWARD F. SHATTUCK and Dr. JOHN A. KILLIAN of New York, presented this paper (by invitation), read by Dr. Killian. The importance of some of the new methods of examination, particularly the *x*-ray, had lessened the use of chemical examinations or rendered the consideration of them less important. Yet an intelligent study of the findings was of value as they often yielded findings in some clinical problems where every bit of evidence was needed. In a series of examinations made at the Post-Graduate Hospital the authors were impressed by the high free hydrochloric acid in cases of gastric ulcer as compared with duodenal ulcer. The average percentage of free hydrochloric acid was under 0.50 in cases of duodenal ulcers. The free hydrochloric acid ranged from 0.53 to 0.80 per cent. in cases of gastric ulcer. In carcinoma of the stomach the average percentage of the free hydrochloric acid was very much under 0.50, reaching that figure in only one instance. A large group of miscellaneous conditions yielded results in which the total percentage of free hydrochloric acid was under 0.50. A second interesting point was the association of hydrochloric acid and lactic acid in cases without retention. It was common to find lactic acid in the gastric contents with retention, and rarely was lactic acid present without retention. In regard to the value of the Wolff-Junghans test: Smithies had reported that next to the Boas-Oppler bacillus a positive Wolff test was the most frequent finding in gastric cancer. This test was present in 80 per cent. of the cases; lactic acid was present in 75 per cent.; the Boas-Oppler bacillus was present in 90 per cent. Of their cancer cases 80 per cent. gave a positive or suspicious Wolff test. The test had been of value in distinguishing the malignant from the benign achylias. Their records of gastric cases had brought out the great value of gastric analysis in the diagnosis of true achylias from psychic achylias. In none of the cases of true achylia gastrica or pernicious anemia were they able to demonstrate the presence of any free hydrochloric acid at any time in the digestive cycle. There were cases that appeared to be true cases that showed when examined that they were spurious or psychic achylias. Undoubtedly functional or psychic factors were present. In these cases improvement was obtained by hydrochloric acid. As regarded enzyme activity of the duodenal contents: Einhorn had shown the value of this procedure in pancreatitis. It gave us qualitative rather than quantitative results. The duodenal contents were obtained by any of the duodenal tubes after test meals and removed at intervals. In 31 cases in which there were two of pancreatic involvement the pancreatic enzymes were present except in the cases of pancreatitis in which the protease was absent and the lipase present in small amount. What they wished to bring out from the data they had obtained was the proportion of the total acidity that was in the form of free hydrochloric acid. In a series of normal cases they found that the free hydrochloric acid formed about 40 per cent. of the total acid in the Ewald meal and about 30 per cent. in the retention meal. It was always less than 50. In a series of cases of gastric ulcer they were impressed with the fact that the total acidity was never very high. In only two cases was there marked hyperacidity. But the constant feature of these gastric ulcers was that the proportion of the free acid to the total was always greater than 50 per cent. and in most cases it approached close to 75 per cent. In gastric carcinoma the free hydrochloric acid ranged from zero up to 40, and in the retention meal it ranged from zero up to 20. Now in these cases of gastric carcinoma it would be observed that there was free hydrochloric acid. Some of the cases gave a high percentage of free hydrochloric acid in which there was an ulcer degenerating into carcinoma. So far as examination of the feces is concerned there are two factors; one is the diastase activity of the stool and the other is the presence of occult blood. In the diastase we have found the normal activity of the stool varies from 25 to 30 per cent. When stools are incubated with starch 30 per cent. of the starch will be converted into sugar. In diseases of the pancreas the diastase activity of the blood is increased, whereas the diastase activity of the stool is either absent or very much decreased. With regard to the presence of occult blood in stools, we have during the past year employed various reagents. We have found the most reliable agent to be benzidin. We formerly procured this product as a grayish powder, but we have procured a product (made by Dr. Fine) which is absolutely white and when dissolved in glacial acetic acid it makes a five per cent. solution and when to this the fecal contents are added we get a definite reaction of greenish blue or deep blue of which there can be no doubt.

Dr. SEYMOUR BASH of New York said he was interested in the presentation of the degree of free acid both in the gastric ulcer, postpyloric ulcer ,and duodenal ulcer, and he thought it was a matter which ought to be either substantiated or thrown out. He thought the question of hypersecretion should have been mentioned, which was important to find out both in the fasting stomach and in the test meal. It was his experience that there was less hypersecretion in genuine organic ulcers than in extraneous diseases such as appendicitis, cholecystitis, and others, especially in the neuroses. He thought the cause of that was vague excitability.

Dr. SOBEL of Rochester said that in cases of ulcer of the stomach or duodenum in which free hydrochloric acid was found, it had never been his experience to find lactic acid. He understood that the authors referred to cases that were undergoing change due to cancerous conditions. The presence of lactic acid meant stagnation fermentation ,and it had always been his belief that free hydrochloric precluded the possibility of lactic acid. He would like to say that it was a matter of great pleasure in these days, when the *x*-ray had been so enthusiastically received in the diagnosis of gastrointestinal diseases, to learn that the chemical examination of the gastric contents had not been entirely abandoned.

Practical Clinical Examination of the Upper Gastrointestinal Tract.—Dr. ALLEN A. JONES of Buffalo read this paper. He presented a tabulation of diseases most commonly encountered. (1) Gastric and duodenal ulcer: symptoms—pain was one of the most important manifestations of ulcer. Many times in young women the first symptom was hematemesis. He had noticed pain to be more frequent in men than in women, it was relieved by digestion. It supervened sooner after eating in gastric than in duodenal ulcer. If the ulcer was located far back postprandial pain occurred; the pain was intermittent in those cases with peristalsis. Typical hunger pain was strongly indicative of duodenal ulcer. It was a misery variously felt as a gnawing. The pain of gastric and duodenal ulcers was temporarily relieved by alkalies. Pain simulating hunger pain might arise from extragastric conditions. Vomiting or lavage relieved the pain of ulcer but not the pain from extragastric conditions. In perforation the pain was excruciating and prostrating and was accompanied by increased frequency of the pulse and muscular rigidity; a leucocytosis was found soon after perforation occurred. Pain in the back at or near the tenth dorsal vertebra was an important symptom, as it indicated ulcer on the posterior wall of the stomach. Tenderness due to ulcer was usually present in some part of the epigastric region. A full stomach gave rise to tenderness. Vomiting was not common in ulcer unless stenosis existed. Hematemesis was one of the classical symptoms of ulcer. In some cases of ulcer with hyperesthesia vomiting was present. Fever might be present if there was suppurative peritonitis. Cholecystitis and cholelithiasis: the most important symptoms were irregular temperature and pain and tenderness in the region of the gallbladder. Suppurative cholecystitis might be sus-

pected if there was a decided leucocytosis. If cholangitis accompanied the cholecystitis there was evidence of some degree of jaundice. If rupture occurred there was tenderness over the liver, rising pulse, and shock. The symptoms of cholelithiasis often gave rise to confusion. Indeed, this affection many times was painless and the symptoms might be gastric. Some sensory gastric disturbances might be present, tenderness over the liver was a varying factor, it might be elicited only on pressure or by Murphy's hammer stroke over the liver. Pyloric spasm, turbid bile withdrawn through Einhorn's tube, a trace of bile in the urine, was not infrequently found in gallbladder disease. Gastritis and achylia gastrica: Acute gastritis with its distress after eating should be remembered as a cause of sudden pain in the upper abdomen. The immediate response to lavage and rest and starving gave the diagnosis. Chronic gastritis was caused by bacterial invasion. When the mucous membrane was involved, there was nothing to prevent the growth of the microorganisms, and the condition was prolonged. Microscopically an abnormal number of leucocytes was found. The food is poorly digested as shown by examination of the stools. Duodenitis: Streptococci and colon bacilli were found in the duodenal contents. Catarrhal jaundice had long been considered infectious in nature. The presence of jaundice which gradually deepened without pain was indicative of an inflammatory state of the upper part of the digestive tract. There was stasis of the duodenal contents. how far the pancreatic duct and the pancreas might be involved was difficult to estimate. That infection might extend upward into the liver must not be forgotten. Carcinoma of the stomach: A tumor at or near the pylorus, vomiting, increased peristalsis, loss of weight, etc., stamped the diagnosis. The diagnosis should be made as early as possible. Occasionally an instance was seen where there was no anemia and no pain, no tumor was to be felt, and no ecessive peristalsis was present; the appetite might be maintained, and the tongue clean. In these cases occult blood in the gastric contents and feces, and the radiographic evidence of a filling defect, were suggestive. One examination was apt to be inconclusive, but repeated examinations seldom failed to lead to a conclusion. Carcinoma when involving the cardia usually caused dyphagia. The differentiation from cardiac spasm was important. Pyloric stenosis: The common and important symptoms were copious vomiting of the gastric contents, a prominence in the epigastric region, and the presence of peristaltic waves across the stomach. In cases of benign stenosis there was an absence of blood, and the appetite was good. Acute dilatation of the stomach: This occurred in the course of grave infectious diseases and was recognized by marked gastric distension and sypmtoms of collapse. Lavage was absolutely essential to save life. The differential diagnosis between a benign and malignant stenosis might be worked out by the Wolff test. Gastroptosis: The habitus of the body showed the diagnosis. There was a sense of weight in the abdomen. Patients found it impossible to gain weight. It lowered the powers of the patient. It might be accompanied by one or more motor or sensory disturbances of the stomach. Fluoroscopic and radiographic examinations determined its presence. However, gastroptosis might escape notice at the bedside. It might be diagnosed by inflation of the stomach when its outline could be percussed.

Dietetic Treatment of Disease of Upper Gastrointestinal Tract.—Dr. ARTHUR F. CHACE of New York presented this paper. The functions of the cardiac and pyloric portions of the stomach were brought out by the investigations of Professor Cannon of Harvard University. Peptic digestion occurred only in the pyloric end. Furthermore, if the empty stomach was in a state of contraction peristalsis came on and continued until the stomach was empty. Experiments had shown that fat emerged from the stomach so slowly that it was present in the intestines in the same amount without variance. Carbohydrates emerged rapidly, and the small intestine received a large bulk of carbohydrates. Proteins were not discharged to any considerable degree for an hour or more. In nine out of 16 cases no food had passed out of the stomach in half an hour. In mixtures of fat with protein the protein left the stomach more slowly than it would if alone. In mixing fats with carbohydrates and proteins if proteins were the first element given, they held back the carbohydrates. The average rapidity of discharge increased from fat to protein and from protein to carbohydrates. Rehfuss and others conducted experiments to note the gastric response to various foods, as beef, etc. The fractional method of analysis was used. It was found that milk drunk slowly left rapidly. Milk which had been boiled five minutes formed small flaky curds. It was concluded that boiled milk dietetically is to be preferred. Eggs left the stomach sooner than meat. With beef products the average evacuation time was two hours and a half in an individual with rapidly emptying stomach. Pork products showed an average evacuation time of two hours and three-quarters for rapidly emptying stomachs. Lamb was found to require an average of two hours and a half for a rapidly emptying stomach. Lamb stimulated acidity more than beef or pork. Having in mind these physiological facts regarding normal digestion, we might proceed to the treatment of hyperacidity, subacidity, and other conditions. First, hyperchlorhydria: This was a gastric disorder in which the secretory glands elaborated a gastric juice so high in ferments that it caused symptoms of pain. Hyperchlorhydria should not be confused with a gastric succorrhea in which an increase of gastric juice was secreted without reference to food and in which a large amount might be found in the stomach for several hours; this was more serious than hyperchlorhydria. The ideal diet was one which produced the minimal stimulating effect on secretion and caused the highest amount of hydrochloric acid. Meats containing few extractives answered the purpose well. The diet should be protein, but in the case of animal protein the extractives should be removed. Beef should not be basted. Olive oil before meals and unsalted butter with meals constituted a good form of administering fat. Highly seasoned food, alcohol, uncooked vegetables, and above all the sugars should be avoided. This latter food stuff was perhaps more responsible for producing hyperacidity than any other article in the diet. The great increase in the number of cases of hyperacidity at the present time was due to the increased ingestion of sugar. All sugars increased the gastric distress after meals. They checked secretion but caused osmosis. The presence of hydrochloric acid checked the ptyalin digestion so that dextrine was found in the stomach. Bread should be partially dextrinized. Only finely divided bread should be used. It was better to use cereals with butter than with sugar. It was very desirable to distribute the amount of food evenly taken at each meal in hyperchlorhydria so as to prevent the accumulation of free gastric juice in the stomach. In cases of continued secretion of gastric juice substantially the same methods were in order. Subacidity: This was a gastric disturbance in which the glands elaborated juice so deficient in ferment properties that the stomach did not call for food. In this condition all food should be insalivated. Secondly, it was desirable to utilize any psychic means to make the food palatable. The diet should be made to include substances which stimulated gastric secretion such as meat extractives, and seasoned food, although the amount of protein should be reduced. In cases of atrophic gastritis where there was an entire absence of gastric juice, the dietetic principles used in subacidity must be applied, realizing that gastric digestion must be carried on by the pancreas. No animal protein should be given, and the maximum amount of protein should not be more than 40 grams a day. The diet should be a carbohydrate one. After a period of three months these patients could again take animal protein.

Myasthenia gastrica: This was a functional gastric disorder in which the stomach wall had lost its muscular tone, and the chemical and mechanical reflexes controlling the pylorus permitted stagnation of food in this organ. The condition was one of the most common of gastric disorders. It was characterized by belching after meals and by a feeling of satiety after a small amount of food. The history showed overeating and frequent eating and distention of the stomach with liquids. In outlining the diet the effect of the emptying time should be considered. Only 6 ounces of liquid

should be given at each meal, since this amount was all that was required for the proper mixing of the food. A mixed diet was preferable; carbohydrates in the form of cereals and vegetable purees should be given. The nourishment should be evenly distributed throughout the meals of the day; each meal should be small in amount, so as to avoid overloading the stomach, and independent feedings should be given midway between breakfast and luncheon, and between luncheon and supper. In severe cases the patient should have one hour's rest after meals. Where marked dilatation was present the foot of the bed should be raised. In such cases the stomach should have complete physiological rest for a few weeks, since such thorough rest induced contraction of the stomach to its normal size. Such rest was obtained by duodenal feeding. Eight ounces of warm milk, with an egg injected through the duodenal tube would be found of value. Rectal alimentation did not insure maintenance of nitrogen equilibrium so that duodenal feeding had superseded it.

Gastric ulcer: It was necessary to neutralize the acid, but the food should be soft, so as not to irritate the ulcer. Food should be given every one or two hours, and contain plenty of carbohydrates. In extreme cases of a neurotic type the administration of milk, eggs, and lactose through the duodenal tube was indicated. In patients with hemorrhage from ulcer nothing should be taken by the mouth for three days; on the fourth day milk with lime water was to be given every hour, and then the intervals lengthened. The dietetic treatment of ulcer required individualization. The tendency was to give a full Leinhartz diet. Two important points must be emphasized—that of giving an adequate amount of iron in the food, at least 15 milligrams a day. This iron could be given in a carefully prepared vegetable pulp; second, avoid scurvy.

Cancer: The dietetic treatment of cancer was different from that of ulcer. In this condition meat juices were indicated in order to stimulate the secretion. The food should be made palatable; condiments and alcohol were indicated. Many of the predigested foods could be utilized.

Drug Treatment of Disease of Upper Gastrointestinal Tract.—Dr. WALTER A. BASTEDO of New York presented this paper. With atropine and belladonna a summary of the results obtained by Rehfuss and others was as follows: (1) In ordinary hyperacidity cases atropine had no useful effect in any dose. (2) In continuous secretion cases it might check the secretion, but only in maximum doses. (3) In spasm it might relieve but only in maximum doses. (4) In hunger pains it might relieve, but only in dogs, not proven in man. (5) In diminishing hypersecretion due to extragastric causes it might be useful. (6) In the doses usually employed atropine and belladonna were wholly without effect on the secretory and motor function of the stomach.

Hydrochloric acid: (1) In cases of achylia gastrica a deficiency of hydrochloric acid might be partially overcome by gastric medication. (2) Hydrochloric acid should always be accompanied by pepsin. (3) In the achylia accompanied by diarrhea acid promised good results. (4) When acid produced diarrhea alkalies should be given at the same period but not at the same time, the amount to be required to be judged by the reaction of the urine.

Bitters: (1) In convalescence from acute illnesses bitters should be given provided they were taken within ten minutes before eating. (2) They should be given in bitter doses. (3) In subacidity to promote secretion of gastric juice. (4) In achylia to act as an appetizer. (5) If the patient was in a state of normal nutrition but physically disturbed, they would be useless. (6) In hyperacidity they should not be given. (7) If the stomach and bowels were deranged the bitters might nauseate. (8) The effect on appetite was solely on the taste buds, so that they should never be given in capsule.

Strychnine: In full therapeutic doses strychnine tended to increase the tone of the stomach, the peristaltic response to food, and to promote secretion.

Alkalies: Given for the pain of distention and for contraction pains coming early and coming late. Pain in ulcer which came in three or four hours after eating and was relieved so successfully by alkalies; it was known as hunger pain or empty pain. To understand drug action we should know what we were combating. First, the irritation of food. In cases without pyloric obstruction the pain did not come on when the stomach was filled with food, but only when it was empty, and then the pain was relieved by taking food. In patients with pyloric obstruction the pain might come on at the usual time although the stomach was filled with food; for example, a patient was required to relieve his pain at 5 o'clock every afternoon by malted milk; one day when he had obtained complete relief at 5 o'clock a stomach tube was passed and not only the soda and malted milk but the food he had eaten at lunch was obtained. Therefore the irritation of food is not the cause of pain. What was the cause of pain? In ulcer the contents might be highly acid, and yet there was no pain. A fair proportion of ulcers were not accompanied by hyperacidity. The Mayos had found ulcer in a number of cases of achylia. Could the contact of the acid with an ulcer produce these pains? It was agreed that the acid of the gastric juice secreted by the stomach seldom exceeded one-half of 1 per cent., and this was mixed with mucin and other colloid substances, yet Hearst and others had repeatedly placed hydrochloric acid in stomachs without causing pain, and furthermore hunger pain might be relieved by acids such as lemons. The author had seen a patient who was habitually relieved of pain by lime juice. Therefore, if acid relieved the pain and the same kind of pain came on with hyperacidity, acid did not cause hunger pain. Pyloric spasm would seem in certain cases to give a pain, yet this was frequently present without any pain whatever. Whether or not the pain was due to the passage of acid into the duodenum had not been shown. Hyperstalsis was present only during the digestive period; furthermore hunger pain was relieved by food, though this sets up peristalsis. Hunger contractions, now recognized as normal, occurred at the usual time of hunger pains, and had been assumed to be the cause of hunger pain; they were immediately stopped if any food was placed in the stomach or in the mouth. Contractions were not the cause of hunger pains. Carlson attributed the pain either to tension of the stomach wall or to hyperexcitability. There must be a hyperexcitability of the pain nerves; but radiography had shown that hypermotility and hunger pains occurred at the same time. Alkalies were of little use during the digestive period except when there was accumulation of gas, when sodium was the choice. Alkalies relieved hunger pains and should be given at the time or after the meals. Alkalies did not check adhesion pains.

Dr. HOWARD STOCKTON of Buffalo said that in cases of jaundice from obstruction when that jaundice depended on duodenitis and not upon involvement of the ducts and their branches we might find a complete absence of amylase in the duodenal tract, and then when that duodenitis subsided a reappearance of the amylase. Of course, there would be a certain amount of bile present in the ordinary case of cholangitis, but bile as well as all pancreatic ferments was absent in duodenitis that caused obstruction at the papilla. In the diagnosis of those cases of cancer in which the appetite remained but in which there were nevertheless irritative symptoms, and in which there were no changes in the blood, and when there was doubt as to the diagnosis and when the radiogram did not help, he had found that in benign cases proper treatment would ordinarily give relief in an ulcer case, but in a cancer case the more one treated the cancer the worse it behaved. He would like to ask Dr. Bastedo if in general practice he did not find cases in which there was relief of the symptoms of spasm and hyperacidity by atropine. He thought there were cases which were relieved by safe doses of atropine given by the mouth as well as subcutaneously, and yet thought other cases were not helped by it, and that only dangerous doses produced effects. Dr. Bastedo, in his remarks on the use of alkalies, did not mention that the sodium was more rapidly absorbed and ceased to give relief for as long a time. Magnesium was not quickly evacuated from the stomach, whereas soda gave relief, but with a return of symptoms. He did not think the action of soda was due to the CO_2, as Dr. Bastedo seemed to

believe, nor did he believe that CO_2 would ordinarily give relief to an irritated stomach.

Dr. ABRAHAM H. AARON of Buffalo said repeated fractional gastric analysis in the suspicious cancer cases would show that there was a gradual diminution of the hydrochloric acid. That had worked very well in making a problem diagnosis in a gradually decreasing hydrochloric acid. What Dr. Bastedo had said in relation to atropine was revolutionary. The textbooks all said that motility was decreased by atropine. He said that in hunger contractions the administration of atropine would give relief.

Dr. ROSE of New York said that he had made an analysis of an average sample diet and found that from articles not classed as protein one obtained about 35 grams of protein, so that it was easy to see that a patient could be fed on a diet of that kind without giving him heavy protein food. In the treatment of myasthenia gastrica where we wanted to give small meals of easily digested food, he had found that in giving milk in small amounts we added to the protein in the diet and could practically exclude meat. Therefore we could get these patients to take frequent meals and maintain their weight. There was one point regarding the use of hydrochloric acid which he had never seen mentioned, and that was that it helped in dissolving mucus in the stomach, especially in cases of subacute gastritis. Even in cases where hydrochloric acid was not well borne where we had to reduce the amount to seven drops, hydrochloric acid seemed to relieve the symptoms produced by the mucus.

Dr. ANTHONY BASSLER of New York said it was interesting to note that perhaps not more than five years ago we had not advanced in the knowledge of these things far enough to render possible such a symposium as the society had been listening to. Hyperacidity was one of the most difficult diagnoses to make, and yet generally it was one that was made perhaps more commonly than any other gastric condition. Sugar was one of the most concentrated articles of food we had to deal with. He thought the future would develop an interest as to the infections of the duodenum from the hepatic side rather than from the gastric, because organisms gained access to the circulation and it was the duty of the liver to eliminate them. His experience had been different from that of Dr. Jones in the occurrence of bleeding in ulcer. When one found hematemesis, the diagnosis had already been made. Hematemesis was not an important initial symptoms of ulcer.

Dr. ELIZA M. MOSHER of New York said one thing that had been omitted was the shape of the stomach. She had found a number of cases having a big colon. What did this do to the stomach? In the first place, what caused it? One would find in those cases a separation of the recti muscles at the umbilicus; it would be found in operative cases where the muscles had not held together in women who had borne children, and in people of sedentary habits. In these cases it was very easy to find a hollow below the navel. It dragged the stomach down, distended it, and delayed the emptying time. Auscultatory percussion should be used in the diagnosis to learn the location of the stomach and intestines. In treatment one must put on a suitable support to hold up the colon.

Dr. ALLEN A. JONES of Buffalo said amylase might be absent in cases of jaundice. The fact was that the pancreatic secretion varied, and this variation itself might account for the fact that at times in the duodenal contents with slight jaundice amylase was absent but might be found later. Carcinoma, which was causing stagnation and vomiting, could be relieved as to symptoms by repeated lavage, and these might be a temporary pick-up on the part of the patient. Dr. Bastedo spoke of bicarbonate of soda as the alkali of preference in cases of hyperacidity. The speaker had not had that experience with bicarbonate of soda even in large doses. The relief in hyperchlorhydria from hunger pains which had been afforded by the administration of bicarbonate of soda had been but temporary and had been followed by just as severe pains before the welcome meal came. The use of magnesia would seem to be preferable to soda because it gave longer relief. But bismuth was the remedy that does the most good. A half a teaspoonful to a teaspoonful of the subnitrate of bismuth taken before breakfast would render it unnecessary for the patient to take alkalies during that day.

Dr. BASTEDO wanted to correct the misapprehension that might have been conveyed that soda acted simply by giving off CO_2. In the stomach with distention from gas the latter was not always swallowed air, and in those cases he had seen it act better than magnesia. He agreed with Dr. Jones that magnesia might act better than soda in some of the resistant cases in keeping away the hunger pains for a time. Years ago he gave atropine and belladonna in quite large doses, and it did not give any results, so he gave it up. He found in the laboratory that atropine had to be used in large amounts to get results so that I have a prejudice against it; and then the literature came out favoring atropine and he used it again but it seemed to give no results. He thought bismuth was a wonderful drug, it was a protective to the mucous membrane of the stomach.

SYMPOSIUM ON GOITER.

Joint Meeting with the Section on Surgery.

Practical Points in Goiter Surgery.—Dr. GEORGE W. COTTIS of Jamestown presented this paper. The term goiter was applicable to many conditions. Until some medical genius solved the question of etiology we must aim at better therapy. The three phases of his paper were: Selection of cases, anesthesia, and operative technique. For practical purposes it was sufficient to divide goiters into three classes: toxic, nontoxic, and malignant. Statistics on the relative frequency of the toxic and nontoxic varied because there was no standard rule of classification. In the case of true primary exophthalmic goiter there must be three things—a history of toxic symptoms beginning soon after or even before the recognition of thyroid enlargement, exophthalmos, and parenchymatous hyperplasia. On the other hand, toxic adenomata might form an obvious goiter long before toxic symptoms appeared, and they never caused exophthalmos. These cases should not be classed as exophthalmic goiter even though they had a fatal termination. Physiological goiters of adolescence and pregnancy were medical rather than surgical problems. Adolescent goiters might be prevented by the use of iodine, and a large percentage disappeared without treatment. In general, nontoxic goiters should be given a chance to subside under medical treatment. Even large colloid goiters, if not of too long standing, would respond to medical treatment; the adenomata did not. In some cases the method of anesthesia was the least important part of the technique, in others it was the decisive factor. In removing small goiters any method was advisable. Local anesthesia added to the strain on the operator, prolonged the operation, and in case of hemorrhage was a serious embarrassment. As a routine anesthetic he used Gwathmey's colonic ether. This was valuable because it was administered in bed and the patient turned over and went to sleep without realizing an anesthetic had been given; and then it caused less postoperative vomiting, did away with the face mask, and a minimum amount of ether was used. Local anesthesia was indicated in old people, in cases of large goiters of long standing, and in extremely toxic cases. In extremely toxic cases local anesthesia was the best, and it permitted an estimation of how well the patient was standing the operation. If the patient became restless it was best to discontinue the operation and pack the wound with Dakin's solution and euresol. With local anesthesia it is by no means sufficient to secure analgesia of the field, the patient must be kept comfortable, a comfortable posture maintained, and a tactful nurse should be present to apply ice-cold compresses. Anyone who had operated on toxic cases with local anesthesia had been embarrassed with the thyrotoxic symptoms during anesthesia. The almost universal use of adrenalin suggested that this was a Goetsch reaction, and since the speaker had omitted the adrenalin he had had fewer symptoms of this sort. The technique is now so standardized that a description would be superfluous. Simple goiters might be enucleated. A lobectomy would often reveal the hidden tumor. One should always search both lobes to see that there was some normal tissue left. In all

general operations the posterior lobe should be left in situ. A lobectomy should be done under local anesthesia so as to avoid the recurrent laryngeal nerve. A lobectomy leaving the upper lobes should never be done. Tetany might develop after some surgical operations, especially when one removed the parathyroids. There were four parathyroids, but there might be only one in a given case. One should never remove the posterior capsule. In toxic goiters ligation of the thyroid artery is indicated. Ligations furnished an index of the patient's reaction to operation. On the other hand, in cases of a single encapsulated adenoma a ligation did very little good unless we could palpate and ligate and artery leading to the tumor. It was logical to assume that ligation excited the tumor to activity without removing the blood supply. The most difficult problem was postoperative hyperthyroidism, which was still the chief cause of mortality. It was increased by undue loss of blood, and the speaker intended to transfuse his next patient. The best treatment was undoubtedly preventive, and the most important factor was the surgeon himself.

Surgical Treatment of Hyperthyroidism; Relation Existing Between the Amount of Gland Removed and the Permanence of Relief.—Dr. GEORGE E. BEILBY of Albany presented this paper. His remarks would be confined to the treatment of hyperthyroidism, and did not include cases of simple goiter, tumors, or cysts. There had been a marked lowering of the mortality rate in recent years due to the careful selection of the patient and the selection of time for operation, and of equal importance was the employment of an anesthetist skilled in the management of these cases, and an improvement in technique whereby the time required for operation had been shortened. In reference to the stage operation, it had been his experience that it was difficult to induce patients to submit to more than one operation for the relief of this condition. If they were benefited by one operation, they accepted that; and if they were not relieved they became skeptical of operative relief. There seemed to be an idea that the removal of one lobe was all that was necessary to effect a cure. Experience had proved that patients derived little or no lasting improvement from such operations. If improvement was noted it was usually for only six months or a year, during which time hypertrophy of the remaining gland took place equal to the amount of the gland that was present before. As to the form of preliminary treatment there was no uniformity. In his hands ligation was not a favorable procedure as it necessitated two operations. It had been his experience that wherever a portion of the gland was removed and the circulation of one lobe was left, the reaction was more severe than where a subtotal resection had been done, so he thought a partial resection of the gland was not a safe procedure. The tendency had been to leave behind too much rather than too little thyroid tissue. It would be desirable if some accurate means could be devised to determine the amount of gland to be left in a given case. He believed that not so much depended on the total amount of tissue left as upon its distribution and blood supply; for instance, if one-third or one-fourth of the total amount of the gland tissue remained with a portion of one lobe with undisturbed blood supply, the chances were in favor of a hypertrophy of this portion of the gland tissue taking place and we had a return of toxic symptoms. On the other hand, if the same amount of gland tissue was left as small bits of tissue distributed throughout the gland, there was no likelihood of these pieces of tissue becoming hypertrophied. In conclusion he emphasized the following: First, the removal of one lobe of the thyroid gland in exophthalmic goiter might give temporary relief, but would not effect a cure; second, if only a portion of one lobe was left and its blood supply was undisturbed it hypertrophied and a recurrence of symptoms might be expected; third, with careful preparation and selection of time a complete operation might safely be done in most cases at one time; fourth, where sufficient gland tissue was removed the toxic symptoms promptly and completely disappeared; fifth, this relief was a permanent one if the gland tissue which remained was not left in a condition such that hypertrophy might take place; sixth, the experience in a sufficient number of cases justified the belief that with the removal of the amount of gland tissue referred to no symptoms of thyroid or parathyroid deficiency need be expected.

Differentiation of Tuberculosis from Hyperthyroidism.—Dr. EMIL GOETSCH of Brooklyn read this paper. It was his purpose to bring out encouraging surgical results in an obscure syndrome. He referred to those border line cases in which one was suspicious of tuberculosis, but in which the physical signs and x-ray findings were insufficient for a diagnosis. From a recent study of patients of this kind who were supposed to be suffering from tuberculosis it was his belief that the underlying trouble was hyperthyroidism and not tuberculosis. The reason for believing that these patients failed to improve under medical treatment, under rigid rest cures, that on expert examination little or no tuberculosis was found, and that these patients showed a constitutional hypersensitiveness to adrenalin, that following resection of the gland there was definite improvement, and last, that on histological examination a condition was found which might be called diffuse adenomatosis, in which there was an increase in the connective tissue and in the acini derived from the fetal cells of the thyroid gland—an increase in the metachondrial content. The operation to be selected in these border line cases depended on the type of pathology found in the thyroid gland. He thought the fear of myxedema had resulted in a removal of too little of the thyroid. In fact, it was surprising how much of the thyroid, even up to three-fourths, could be removed without producing hypothyroidism. A margin of gland tissue was left on either side to protect the parathyroids and the recurrent laryngeal nerve. An interesting differential point was that whereas the tuberculosis case responded promptly to rest and hygiene, these mild thyroid cases were not improved after prolonged rest. The hyperthyroid cases felt better at rest, but they could not resume activity without bringing on the symptoms of which they had complained.

Surgical Treatment of Exophthalmic Goiter.—Dr. EDWARD STARR JUDD of Rchester, Minn., read this paper. In the Mayo clinic, he said, no cases of exophthalmic goiter were called such without hyperplasia and enlargement of the gland. It was a condition of toxemia under control of the cells of the thyroid. Hyperplasia was definitely shown by increase in the size of the gland, and when a part of the gland was removed the symptoms subsided; when the symptoms returned they found that the remaining part of the gland had enlarged. In recent years the greatest improvements had resulted from a better understanding of the disease in its clinical aspects. Hyperthyroidism occurred in cycles with exacerbations of the symptoms and remissions. The time to institute surgical treatment was when the patient was in a remission, never when the symptoms were increasing. Many patients could be carried over the exacerbations by rest in bed and palliative treatment, injections of boiling water, quinine and urea, and ligation which was palliative. No matter how well these patients might appear following palliative treatment, it was always best to advise a thyroidectomy, as the danger of a relapse would thereby be materially reduced. Recently he had depended on the clinical picture to measure the toxicity, but changes in the basal metabolism now gave better results. Cures should not be reported within a short time after the subsidence of symptoms. The operation now performed was a subtotal thyroidectomy by which changed thyroid tissue was removed. This operation had the advantage of leaving a symmetrical scar, whereas lobectomy did not.

In conclusion, at the present time we were more than ever impressed with the action of the thyroid and by keeping this in mind rational treatment might be carried out. While medical treatment, x-ray exposures, and radium modified the disease, it was not certain just how much they altered the natural course of hyperthyroidism, whereas subtotal thyroidectomy removed changed tissue and as a result the metabolism rate was reduced to approximately normal and the symptoms subsided very quickly in a large majority of the cases.

Dr. C. C. WEBB of Clifton Springs said they had been following these cases for four years from every possible angle. They had done metabolism tests, and sugar tolerance tests, and adrenalin tests. They used the Benedict portable apparatus. The same confusion had

come in here as always came up, and that was what was meant by hyperthyroidism. And the same confusion came up as regarded classification. These cases that Dr. Goetsch was talking about did not show an increased metabolism test unless one put them to an increased metabolic activity. The metabolism test was quite as delicate as the adrenalin test. The metabolism test was of most value in determining the amount of hyperacidity in the extremely toxic cases whether they were due to adenomata or to exophthalmic goiter. It was of importance to determine how long one could keep that patient in bed and whether one could ligate one or two arteries at a time; and as a diagnostic test the speaker was inclined to regard it as of more importance than the adrenalin test. He would like to ask Dr. Judd how he regarded infections of the thyroid gland and how they affected the hyperthyroidism symptoms. Infections of the thyroid might be one of two forms, either a large collection of pus or a series of small abscesses in the various acini of the gland.

Dr. Samuel W. Bandler of New York asked why goiter was eight times more common in women than in men? He was interested in this subject as a gynecologist. In trying to find an explanation for the nervous symptoms in women he asked them, "How many days before you menstruate do you know that you are going to menstruate?" Some did not know, others said they had a feeling in the breasts, but the vast majority would say that five or six days before menstruation they were irritable and cross. Now that was due to hyperthyroidism in the largest number of cases, and the way a woman behaved before her menstruation was an index of what gland was sensitive. Now if one looked over one's children one will find that they were irritable at times, but no one seemed to realize that it happened every four weeks. Think of the injustice that had been done to children by not realizing that fact. The Goetsch test proved that there was no such thing as a uniglandular trouble. Adrenal cortex was going to take the place of adrenalin. There was a reason why Dr. Cottis feared to use adrenalin in his local anesthesia on the thyroid. The glands were all interrelated. We all knew that if we took thyroid extract it could do harm. Now there was not an endocrine used that could not do harm if used for the wrong thing. There must be a balance between all the endocrines and each endocrine. Now here was a thing that concerned the medical profession: We were on the verge of what we now thought was going to be a revolution in medicine; we were on the verge of endocrine experimentation, and every one of us was going to try endocrines. Now, then, why not try to correct what was going to be a very serious fault? The public were going to learn about these gland preparations, and were going to go to the druggist and buy them of their own accord, without a prescription. Now, what Dr. Bandler said he was asking for was the appointment of a committee selected from the various sections and added to that a like number of men outside of New York state to talk over this thing and to bring it to the attention of the American Medical Association, so that some action might be taken to prevent the selling of endocrine preparations without a physician's prescription.

Dr. George E. Beilby of Albany wished to say a word with reference to the symptoms of exophthalmic goiter. It had been his experience that exophthalmos was a late symptom. He thought the impression had gone abroad among medical men that unless there were very definite eye symptoms the case was not one of exophthalmic goiter; that was a very wrong impression, and it was desirable to get cases before they developed exophthalmos.

Dr. Emil Goetsch of Brooklyn did not know whether he could cover all the points which had been broached. However, he might bring up a few of them with reference to clearing up certain impressions which were evidently in the minds of some as to what he had really claimed. Now, with regard to the adrenalin test, as such, he had never said that a positive adrenalin test meant positive hyperthyroidism. He had repeatedly insisted that that was not the case. He would say that he believed that every case of hyperthyroidism would give this test, and if it was negative it was not hyperthyroidism. He had had six years' experience with this test, and had yet to find a case that violated those two statements. Now then there came a certain percentage of cases that gave a positive reaction. What the reaction meant—it was a combination affair between the thyroid and the adrenal, and the sympathetic nervous system. The test depended on all those. Whenever there was an increase of the thyroid secretion in the circulating fluid of the body it sensitized the nervous system to adrenalin. Hyperthyroidism was the one disease that did that. He ventured to say that the great majority in which that held true were cases of hyperthyroidism. In hyperthyroidism the symptoms following the test lasted an hour to an hour and a half, and there was a manifestation of the symptoms of the disease. Now, in certain neuroses there was a typical reaction in which there was a sudden rise of the pulse, with an almost instantaneous return to normal. Whereas the very characteristic symptoms of hyperthyroidism, such as flushing of the face, did not occur. So granted there might be 5 per cent. of cases that were confusing, they were again distinguishable by a very careful physical examination and a carefully taken history. Like every test, this was not fool proof. One had to use his mind. What was hyperthyroidism in the first place? He did not mean disease of the thyroid. It was a functional condition of the thyroid. We were not talking about toxic adenomata or puberty hypertrophy. It meant that we had too much of that toxic product in the circulation. Now there was no doubt that every one of us would get an adrenalin response if we were frightened. Dr. Cannon had shown that in animals which were frightened there was an increase of adrenalin in the circulating blood. Some of these transitory reactions might mean hyperthyroidism. Soldiers who were frightened to death had hyperthyroidism. So with these patients, we had to have their confidence, and must have them at rest in bed, because if we did not they would already have an adrenalin reaction. With reference to hypersensitiveness in conditions other than hyperthyroidism: It did occur in neurocirculatory asthenia, but one of the differences was that in neurocirculatory asthenia they could not remember the day when they were really well, whereas in hyperthyroidism they had a starting point. It was a question whether hyperthyroidism occurred before puberty, whereas neurocirculatory asthenia did begin before puberty.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

California State Board of Examiners.

October, 1919.

(*Continued from page* 592.)

PATHOLOGY AND BACTERIOLOGY.

(Answer ten questions only.)

1. Define the following terms: Anemia, embolism, thrombosis, toxin, ptomaine, leucomaine, glycosuria, hemorrhage, edema, inflammation, atrophy, degeneration, necrosis, tumor.

2. Give the etiology, microscopic pathology, and results of an acute endocarditis.

3. Give the etiology and differential diagnosis of enlarged cervical lymph glands.

4. Give the etiology and morbid chemistry of fatty degeneration.

5. Name two malignant and five benign tumors.

6. Give the differential diagnosis in the gross between a malignant and benignant tumor.

7. Name the types of pneumonitis. Give the differential diagnosis gross and macroscopic between lobular pneumonia and multiple hemorrhagic infarcts of the lung.

8. What is the difference between active and passive immunity? Give an example of each.

9. Name four methods by which active acquired immunity may be produced artificially and give an example of each method.

10. What is tuberculin? Why does the injection of tuberculin fail to produce a reaction in a healthy person? Why does it produce a reaction in an individual affected with tuberculosis? Why may it fail to produce

a reaction in an individual that has recently reacted?

11. Explain what is meant by complement fixation and describe briefly the elements and principles involved.

12. Describe in detail how you would make a diagnosis in a case of suspected diphtheria; also name the organisms that might be mistaken for the Klebs-Loeffler bacillus.

SURGERY.

1. Discuss acid intoxication following general anesthesia, its etiology, prognosis, prophylaxis, and treatment.

2. Draw schematic diagram, anteroposterior, of a Pott's fracture. Give treatment in detail.

3. Give the indications for operation in traumatic insanity.

4. Discuss congenital talipes: (*a*) Theories as to cause, (*b*) varieties, (*c*) when should treatment be instituted, (*d*) briefly describe treatment.

5. Give the diagnosis of stone in common duct. Describe in detail the surgical treatment.

6. Describe the pathology in dislocation of femur (hip joint). Name the varieties and give treatment for one.

7. When is taxis contra-indicated for the reduction of strangulated hernia. Describe its application in strangulated, oblique, inguinal hernia.

ANSWERS.

PATHOLOGY AND BACTERIOLOGY.

1. *Anemia* is a diseased condition in which the blood shows a diminution in the number of red corpuscles, or in the amount of hemoglobin, or in both red cells and hemoglobin.

Embolism is the obstructing of a blood-vessel by the lodgment of a foreign body.

Thrombosis is the coagulation of blood within the vessels during life.

Toxin is a poisonous product of bacteria.

Ptomaine is a product of bacterial activity on dead protein matter.

Leucomaine is a basic product of cell metabolism occurring in the tissues of living animals.

Glycosuria is a condition in which sugar is discharged in the urine.

Hemorrhage is the escape of blood from the vessels.

Edema is an accumulation of serous fluid in the tissues of the body.

Inflammation is the name given to the series of changes which occur in a part as the result of injury, provided that the injury does not at once destroy the vitality of the part.

Atrophy is a decrease in the amount of tissue owing to a diminution in the number or size of the elements of which it is composed.

Degeneration is a morbid condition in which the cell protoplasm is gradually changed into a new material.

Necrosis is the complete and permanent arrest of nutrition of a part.

Tumor is an atypical new formation not the result of inflammation.

2. ACUTE ENDOCARDITIS. *Etiology:* Simple endocarditis is associated with rheumatism or scarlet fever. Malignant endocarditis is also associated with rheumatism, scarlet fever, and also with pneumonia or septic processes. Micrococci are often found.

MALIGNANT ENDOCARDITIS. *Pathogenesis:* "Diplococcus of Poynton and Paine, *Streptococcus pyogenes, Staphylococcus pyogenes aureus, Diplococcus pneumoniæ,* gonococcus, and *Streptococcus viridans* are the chief bacteria found; but others have also been observed in this condition. Their etiological significance is not settled.

Morbid Anatomy: In the simple form there will be found a cloudiness, followed by edematous thickening of the valvular endocardium; superficial erosions, and the formation of small granulations; deposits of layers of fibrin and corpuscles from the blood, the whole process resulting in the formation of small warty vegetations. These vegetations are most marked at a slight distance from the free borders of the valves—*i.e.*, those parts which come into apposition during closure. In course of time they are transformed into fibrous tissue. According to Poynton and Paine the infective organisms are conveyed to the base of the valves by the capillaries, and thence pass to the subendothelial tissues by the minute nutrient channels in the valvular substance; others hold that the organisms are derived from the blood circulating over the surface of the valves. In the malignant form the initial changes are similar, but there are some important differences, inasmuch as ulcerations may completely replace the vegetations. The differences are: (1) The vegetations when present are larger and fungating. (2) The underlying tissues are necrotic and show loss of substance and round-celled infiltration. (3) They contain masses of micrococci, while in simple endocarditis the organisms are scanty. The two forms cannot be distinguished by the organisms producing them; either simple or malignant endocarditis may arise from a pyogenic infection. (4) When the vegetations become detached they form *septic* emboli, giving rise to metastatic abscesses. (5) The ulcerative process causes great destruction of the valves, and may even lead to perforation of the curtains. (6) The subsequent or permanent changes in the valves, if the patient survive, are much more marked. (7) If the vegetation touches the mural endocardium as it flaps to and fro, the part touched becomes affected by contact.

Microscopical Changes.—The vegetations are seen to be nonvascular, structureless masses composed of fibrin and fused blood-plates; bacteria may or may not be present. If the inflammation is severe on or near the mitral valve it may spread to the chordæ tendineæ and papillary muscles. Hyaline degeneration, coagulation, necrosis, or round cell infiltration may be found in the endocardium."—(Wheeler and Jack's *Handbook of Medicine.*)

3. *Enlarged cervical lymph glands*—"In *chronic simple lymphadenitis* some source of continuous irritation in the area drained by the lymph glands may be discovered. Although the glands are enlarged and perhaps tender, they do not tend to mat together or to suppurate. Removal of the source of irritation results in cure. If recovery does not follow appropriate treatment, a strong suspicion of tuberculosis should be entertained. *Tuberculous lymphadenitis* progresses despite local treatment, and successively involves gland after gland. The glands show a strong tendency to adhere to each other and to the skin, and to undergo caseous degeneration. The condition is most common in children, in whom other signs of tuberculosis may be recognized. The family history is of some importance. *Syphilitic lymphadenitis* is diagnosticated by the history of a sore, by associated lesions of syphilis, by the Wassermann test, and by the results of treatment. The glands are hard, discrete, not adherent to each other or to the skin, do not tend to suppurate, and are neither painful nor tender. The enlargement in the primary stage is confined to the glands anatomically related to the sore; during the secondary period the distribution is general, the epithrochlear and post-cervical glands always being involved; in the tertiary period the glands may become gummatous, the diagnosis then resting upon the history and the results of treatment." (Stewart's *Manual of Surgery.*)

4. FATTY DEGENERATION. *Etiology.*—"Grave depression of the vital activity of a cell—leading to (1) too rapid destruction of protoplasm, (2) lessened ability to repair losses, and (3) impaired oxidizing power. This depressed vitality is always the *proximate cause,* and is usually induced by (*a*) alteration in the quantity and quality of food brought to the cell; or (*b*) by change in the physical condition of the cell; or (*c*) by the gradual but natural death of the cell, for there is a natural limit to the life of a single cell, as there is to the life of the whole organism."—(Greene's *Pathology.*)

Morbid chemistry.—"Fatty degeneration represents either or both of two conditions: (1) It may result from an increase in the normal quantity of fat in an organ undergoing parenchymatous degeneration, through an infiltration of fat from the outside; this is particularly true of the fatty degeneration of the liver; (2) or there may be no increase in the total

amount of fat, but the invisible fat becomes visible through autolysis of the cell proteids. (3) Finally, of course, both factors may occur together. Of these various forms, in only the first and last can we properly consider the organ fatty," and the form that will occur seems not to depend upon the cause of the cell injury, but rather upon the organ under consideration."—(Wells' *Chemical Pathology.*)

5. *Two malignant tumors.*—Carcinoma and sarcoma. *Five benign tumors.*—Lipoma, chondroma fibroma, myoma, and adenoma.

6. "*Benign* tumors are usually very slow in growth and distinctly localized, having a definite capsule. They rarely attain excessive size, but occasionally, owing to their intrinsically benign character, may attain huge dimensions without injury to the general economy. Generally they are movable (unless bound down by surrounding inflammatory tissue or primarily attached to bone). They do not metastasize or become disseminated throughout the body, and when completely removed do not recur. They exert no influence whatever upon the general economy when favorably situated, but may endanger life by their size and situation when they interfere with the normal functions of any of the important organs of the body.

"*Malignant tumors* exhibit diametrically opposite characteristics. They grow rapidly and usually diffusely. They are not encapsulated and may quickly attain considerable size, although huge malignant tumors are rather exceptional, since they usually prove fatal before they attain such proportions. They are intimately connected with the surrounding tissues and quickly become bound down and immovable. They metastasize and become disseminated rapidly through the lymph or vascular system, progressing steadily toward a fatal termination by the interference with vital functions caused by metastatic growths, or by an autointoxication which undermines the general health and produces the condition commonly known as cachexia."—(Rodman's *Diseases of the Breast.*)

7. *Types of pneumonitis.*—Lobar pneumonia, lobular pneumonia, broncho-pneumonia, interstitial pneumonia, tuberculous pneumonia, syphilitic pneumonia, also aspiration pneumonia and septic pneumonia.

Lobular pneumonia.—"At first dark red in color, the lobular areas of consolidation in broncho-pneumonia become more gray at the center through degeneration of the exudate, while the advance of the process in the periphery is marked by a less solid, redder zone. On section of the fresh lung these areas usually project somewhat above the general surface, and at their centers the involved bronchi may appear as lighter spots, from which pus may exude or be easily pressed out. Such areas may coalesce, forming larger consolidations. The exudate, which more or less completely fills the air spaces, consists of serum, old and new-formed epithelial cells from the walls of the air-spaces, red blood cells, and often fibrin and polymorphonuclear leucocytes with various forms of microorganisms. As a rule, however, fibrin and leucocytes are not as abundant as in the exudate of lobar pneumonia. Mucus and bronchial epithelium may be aspirated into the air spaces and mingled with the exudates."

Hemorrhagic infarct of the lungs.—"These infarcts are often multiple, usually circumscribed and rounded or wedge-shaped, from the size of a walnut to that of an orange. They are of dark red color, hard and unaerated, with the air spaces distended with blood, and are often surrounded by a zone of inflammatory exudate. They may be situated in any part of the lungs, but are most common in the lower lobes. At the apices of the infarcts, the occluding thrombus or embolus may be discovered. When, as is usually the case, they are near the surface of the lungs, a circumscribed inflammation of the pleura often occurs. The air spaces within the infarcts are filled with blood and the capillaries distended."—(Delafield and Prudden's *Pathology.*)

8. *Active immunity* is that form of acquired resistance to infection which is brought about by the activity of the cells of a person or animal as a result of having had the disease, or as a result of artificial inoculation with a modified or attenuated form of the causative microorganism.—*Example.*—Vaccination against smallpox.

Passive immunity is that form of acquired immunity which depends upon defensive factors not originating in the person or animal protected, but is passively acquired by the injection of serum from one that has acquired an active immunity to the disease in question. It is a sort of secondary immunity acquired by virtue of having received antibodies actively formed by another animal that has had to resist the infecting agent in order to produce them. *Example.*—Prophylactic use of diphtheria antitoxin.—(From Kolmer's *Infection, Immunity,* etc.)

9. *Four methods by which active acquired immunity may be produced artificially.*—(1) *By accidental infection,* such as that which follows an attack of an infectious disease such as scarlet fever, measles. (2) By *inducing an attack of the disease* by artificial inoculation; this is mostly used in veterinary practice, where animals are inoculated with a mild form of a disease (such as Texas fever) in order to produce immunity against a graver form of the disease. (3) By *vaccination,* such as is practised against smallpox. (4) By the *use of bacteriolysins,* as in typhoid vaccination.

10. *Tuberculin* is a glycerin extract of cultures of the bacillus of tuberculosis. It is used as a means of diagnosis of tuberculosis. The reason for a reaction in the case of a tuberculous person, and the absence of such reaction in the case of a well person is thus given by Kolmer: "The antibody-like substance produced by the (tubercle) bacilli and diffused through the tissues enters into combination with the tuberculin, giving rise to the formation of a toxic substance in the general circulation, as well as at the point of inoculation of the tuberculin. The tubercle bacilli are considered as stimulating the body-cells to produce an antibody or a "ferment" in the nature of an amboceptor, which splits the tubercle protein contained in tuberculin, liberating a protein poison, which produces a general, local, and focal reaction."

11. *Complement fixation.*—"The reaction depends upon the fact that when an antigen, *i. e.*, a substance capable of stimulating the formation of antibodies in animals or man, is mixed with its inactivated antiserum, in the presence of complement, the complement is firmly fixed by the combined immune body and antigen in such a way that it can no longer be found free in the mixture. If such a mixture is allowed to stand at a suitable temperature for an hour or more, and to it is then added an emulsion of red blood cells together with a suitable quantity of inactivated hemolytic serum, no hemolysis will take place, since there is no free complement available to complete the hemolytic system. If, on the other hand, the original mixture contains no antibody for the antigen used, the complement present is not fixed and is available for the activation of the hemolytic serum later added. The reaction thus depends, in principle, intimately upon the fact that neither antigen alone, nor amboceptor (antibody) alone, can fix complement, but that this fixation is carried out only by the combination of antigen plus amboceptor. Any specific amboceptor can be determined by this method, provided the homologous or stimulating antigen is used; and *vice versa,* by the use of a known antibody a suspected antigen may be determined."—(Hiss and Zinsser's *Bacteriology*).

12. A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily obtained in pure culture. Loeffler's blood serum, particularly with the ad-

dition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C. *Method of staining:* It stains with any aqueous solution of an aniline dye, and quite characteristically with Loeffler's alkaline methylene blue. Neisser's stain is also recognized. The bacilli also stain well by Gram's method.

The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline methylene blue.

Other organisms which may be mistaken for the diphtheria bacillus are: Pseudodiphtheria bacilli and xerosis bacilli.

SURGERY.

1. *Acid intoxication following general anesthesia.*—"In certain cases in which dangerous symptoms arise after anesthesia, the urine contains albumin, casts, and either diacetic acid or acetone or both of these substances. Acid intoxication is very much commoner after the administration of chloroform than of ether, but may follow the giving of any general anesthetic. It may occur in individuals whose tissues contain areas of fatty degeneration, but it also occurs in those entirely free from degeneration; in fact, children particularly suffer in this way after the use of chloroform. The actual operation has nothing to do with the trouble, and sepsis is not causative. The drug used as an anesthetic causes acute fatty degeneration of the liver, quantities of toxins are formed, and these toxins cause the symptoms. Acetone, diacetic acid, and beta-oxybutyric acid are by-products of the process and are antecedents or precursors of acetone. The symptoms arise after the patient has emerged from anesthesia and reacted from shock. There is persistent vomiting of thin and foul fluid, the patient is extremely restless and much excited, there may be delirium, but dulness and heaviness may take the place of restlessness and excitement and coma may arise. Usually the temperature is subnormal, but sometimes there is elevated temperature. In many cases jaundice arises. There is an odor of acetone on the breath. The urine contains albumin and casts, and either diacetic acid or acetone or both. Some cases recover, but most of them die in from one to five days. A knowledge of this condition explains some otherwise inexplicable deaths, and also some cases of retarded convalescence. In acid intoxication there is fatty degeneration of the kidneys, of the liver, of the suprarenal glands, and of the gastric mucosa. The occurrence of such a condition is an impressive admonition that a surgeon should operate quickly, that as little of the anesthetic should be given as possible, that the urine should be carefully examined each day after operation for certainly several days, and that chloroform should not be used for prolonged administration. Severe acid intoxication is treated as follows: Encourage skin activity by wrapping the patient in blankets and surrounding him with hot-water bags. Give salt solution with bicarbonate of sodium by hypodermoclysis and by the rectum. In mild cases of acetonuria simply give sodium bicarbonate by the stomach."—(DaCosta's *Modern Surgery.*)

2. *Pott's fracture* is very common, and is due to indirect violence, such as turning over on the inside of the foot. The strain tears through the internal lateral ligament of the ankle or tears off the tip of the malleolus; then the astragalus is pressed against the inner side of the external malleolus by the continuation of the violence. The fibula is overbent, and breaks about three inches above the tip of the malleolus. At the same time the foot is displaced outward or outward and backward. In many cases, however, the displacement is slight.

Treatment.—"An anesthetic should always be given, and the fracture reduced by relaxing the calf muscles and applying traction to the foot. The limb must then be fixed on the back splint, with side splints in addition. The foot must be at right angles to the leg, the bony points in line, and the posterior displacement corrected. The surest way of maintaining the foot in good position is to at once apply plaster of Paris. Other splints used are Dupuytren's and Syme's horseshoe splint. Massage and passive movement at the end of ten days are advisable, the fragments being firmly grasped to prevent displacement."—(*Aids to Surgery.*)

3. *Indications for operation in traumatic insanity.*—We should operate on cases "in which insanity has soon followed a head injury; if the site of the trauma is indicated by a scar, a depression of bone, local tenderness, fixed headache, or some localizing symptom—motor or sensory—operation should positively be undertaken. In a case in which the insanity has developed later, in which the intermediate period between the injury and the development of the insanity has shown the change from the normal mode of thinking and way of acting previously alluded to, and in which the site of trauma is indicated by any of the evidences mentioned above—operation should positively be performed. One should not operate upon a case simply because there is a dubious record of an antecedent fall or blow, which merely suggests the possibility of a traumatic origin for the insanity. In any case in which there are positive signs of increased pressure it may be considered proper to trephine as a palliative measure."—(DaCosta's *Modern Surgery.*)

4. *Congenital club-foot.*—By club-foot is meant a deformity of the foot due to muscular, ligamentous, or osseous causes, the displacement occurring mainly at the ankle and mid-tarsal joints. It may be congenital or acquired. *Congenital malformation* is responsible for a certain percentage of the cases, resulting from imperfect formation of the bones of the foot, occasionally from absence of the lower end of the tibia or fibula, or very rarely from intrauterine paralysis of central origin. Other cases are due to malposition of the feet *in utero*, possibly resulting from a deficient amount of liquor amnii, as a result of which the feet are abnormally compressed and held in one position. Naturally the legs of the fetus are in a state of flexion, and the feet usually in a position corresponding to that of talipes varus; it is easy then to understand that in an unusually small uterus this position may become fixed. Spina bifida in the lumbar region is occasionally associated with congenital talipes, which is then probably due to impairment of nervous control. The congenital variety is often hereditary, and may occur in several members of the same family, or be transmitted through many generations.—(From Rose and Carless' *Surgery.*)

Varieties of talipes: Talipes equinus consists in extension of the foot, with spasm or shortening of the Achilles tendon, and usually with a loss of power in the anterior tibial group. *Talipes varus* is an inversion of the foot, associated with rotation at the midtarsal joint. *Talipes calcaneus* is characterized by elongation of the tendo Achillis and of the muscles associated therewith, by shortening of the anterior tibial group of muscles, and by slight flexion of the toes. *Talipes valgus* is a deformity of the foot in which eversion is a prominent feature. *Talipes cavus* results from bony subluxation at the midtarsal joint and contraction of the plantar fascia, and produces an exaggeration of the normal transverse arch of the foot.

Talipes equinovarus is a deformity in which the heel is drawn up, and the anterior part of the foot is inverted and drawn inwards.

Treatment.—"It may be treated in the early stages by fixing the foot in good position by a series of plaster of Paris casings, or by using a malleable metal splint. Tenotomy of tendons which hinder reduction in some cases is necessary, with the subsequent application of plasters. If the ligaments on the inner side of the ankle hinder reduction, they should be divided. In the neglected cases, where the patient has been walking on the outer side of the foot, tarsectomy is necessary. A wedge of bone, with its base outwards, is removed by a chisel or saw, irrespective of the joints, from the tarsus in front of the peroneal groove on the cuboid. The foot can then be brought into good position and maintained so by plaster of Paris."—(*Aids to Surgery.*)

5. *Gallstones.*—"While the calculus remains free in the gall-bladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right hypochrondiac or epigastric region, frequently radi-

ating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, sex, history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber-colored urine, containing bile, and sometimes the finding of the stone in the feces.

"*Cholecystotomy*, or opening the gall-bladder, is done through an incision parallel to and 1½ inches below the costal margin over the gall-bladder. The liver is drawn up and the intestines packed away with gauze. If the gall-bladder is distended, the fluid is removed by tapping it with a trocar and cannula. The opening is then enlarged, and the stones are removed with a scoop. The bile-ducts are examined along their whole course by a finger externally, and by a long probe internally. If the interior is fairly healthy, the opening is sutured with two layers of continuous sutures and the abdomen is closed. Usually it is necessary to drain the gall-bladder for a time, in which case the margins of the opening are stitched to the peritoneum and transversalis fascia of the abdominal wound. The fistula thus established soon closes if there is no obstruction to the passage of the bile into the intestine. If not, it must be closed by a plastic operation or cholecystenterostomy."—(*Aids to Surgery.*)

6. *Pathology of dislocation.*—"Dislocation is a displacement of the articulating ends of the bones entering into the formation of a joint, with rupture of the ligaments. The immediate effect is the occurrence of some hemorrhage, followed in uncomplicated cases by absorption of the blood and connective-tissue proliferation by which repair is brought about. The changes vary according to the position of the bones. If the bone enters its normal position again—that is if the luxation be reduced—the subsequent changes amount to no more than a *restitutio ad integrum*. If the luxation be not reduced and the displaced bone remains in an abnormal environment, somewhat complicated changes occur. Those tissues pressed upon by the bone atrophy. The articular end, no longer in conjunction with its fellow, becomes covered with connective tissue that chiefly develops from the lacerated capsule. The cartilage becomes fibrillated and gradually changes to connective tissue. New bone is formed, and the condyle of the articulating end becomes diminished in size. The proximal bone also suffers. If, however ,the two bones come together in an unusual position, either they unite by ankylosis or a new joint is formed. This is accomplished through the excavation of the bone by pressure atrophy, and partly by a surrounding bony reinforcement caused by ossifying periostitis. The surrounding connective tissue forms the analogue of the capsular ligament. A synovial membrane finally develops, and a true nearthrosis results."—(McFarland's *Pathology.*)

The *varieties of dislocation of the hip*, are: *Backwards*, (1) on to the dorsum of the ilium, (2) on to the sciatic notch; *Forwards*, (3) on to the obturator foramen, and (4) on to the pubic bone. *Treatment:* In posterior luxation of the hip joint the patient should be placed on a mattress on the floor, and then be anesthetized. The leg is then to be flexed on the thigh, and the thigh flexed on the abdomen; adduction is to be increased so that the knee is beyond the middle line of the body; then abduct, freely circumduct outward, and finally extend the limb so that it is parallel with the other.

7. "In treating *strangulated hernia* place the patient upon his back, bend the knees over a pillow, and rigidly interdict the administration of food. In applying *taxis*, flex and adduct the thigh of the affected side. Always lower the shoulders and head, and raise the pelvis, and accomplish this by lifting the foot of the bed and placing pillows under the pelvis. Grasp the neck of the sac with the fingers and thumb of one hand, and employ the other hand to squeeze the hernia and urge it toward the belly; in *oblique inguinal* hernia the pressure should be upward, outward, and backward. If the bowel is reduced, it passes from the hand with a sudden slip and enters the belly with an audible gurgle; omentum, when reduced, slowly glides back without gurgling. Taxis is never to be continued long, and *it is not even to be attempted* in cases of great acuteness, in cases where strangulation has lasted for several days, in cases known to have been previously irreducible, in cases associated with stercoraceous vomiting, or in inflamed or gangrenous herniæ."—(Da Costa's *Modern Surgery.*)

Therapeutic Hints.

Creosote Inunctions in Pneumonia and Influenza.—John E. B. Wells, in 1898, used the axillary inunction of creosote in a severe case of pneumonia. Within half an hour the patient sweated, and the temperature fell from 104° to below 100°. Uninterrupted recovery followed. Since that time he has made frequent use of this method, with almost unvarying success. He considers the results too constant to admit of the change in the patient's condition being merely a coincidence with the crisis occurring at the time of the administration of this treatment.

The method of administration is simple. For adults, 10 minims of pure creosote are gently rubbed into the right axilla with the finger. If necessary, which he has found to be rarely the case, a second dose may be given, this time in the left axilla, for fear of blistering. The patient must be dressed in woollen or flannel and placed between blankets so as to avoid a chill after the sweating which follows the inunction. Only slight discomfort attends the treatment, a slight burning of the skin, which passes off in a day or two without vesication, being the only disagreeable effect. For children he dilutes the creosote with soap liniment, reducing the proportion of creosote according to the age of the patient. For infants, in place of the axillary inunction, he has at times substituted rubbing the back and front of the chest with a liniment containing creosote.

Practically all cases of influenza under Wells' care have been treated by rest in bed, plenty of fresh air, and the administration of creosote by the mouth. Half a minim of creosote shaken up with half an ounce of water is the simple mixture. The addition of half a minim of oil of peppermint makes it more palatable. Very few cases treated in this way developed pneumonia. When the signs of pneumonia developed the axillary inunction of creosote was nearly always followed by its abortion, or it was so modified that the patient recovered. When the pyrexia of influenza has gone, quinine or strychnine, or both, may be necessary.—*British Medical Journal.*

Digitalis in Cardiac Affections.—G. Canby Robinson made a study of the rapidity and persistence of the action of digitalis on hearts showing auricular fibrillation in a series of 26 cases. Large single doses of the tincture of digitalis were administered by mouth. The drug used was standardized and was usually given in doses ranging from 15 c.c. to 25 c.c. The study of these cases demonstrated that such doses of digitalis affect the heart of cases of auricular fibrillation or flutter at a relatively constant time after administration, in from two to five hours, indicating that the drug is absorbed from the alimentary tract at a fairly rapid and uniform rate. The series of cases also demonstrated that the maximum effect on the heart is usually obtained in about twenty-four hours, and generally continues to be effectual for from four to fifteen days, or on an average of nearly ten days.—*American Journal of the Medical Sciences.*

Acute Eczema.—In acute papular or papulovesicular eczema the skin is is often so irritable that salves and ointments as well as pastes are poorly tolerated. In these instances applications of a mild alcoholic solution of 0.5 per cent. of salicylic acid followed by the use of a bland dusting powder are indicated every three or four hours.

Salicylic acid	1	2
Diluted alcohol	240	

Label: Apply to affected parts.

Starch	
Talcum	āā 60

Label: Use as dusting powder.

Should the papules prove resistant after the eczematous outbreak has been controlled by this treatment, the following may be used:

Zinc oxide		
Talcum	āā	15
Petrolatum		30

Label: Apply to inflamed parts.

Zinc oxide	
Starch	
Glycerin	
Distilled water	āā 15

Label: Zinc oxide lotion.

Under this treatment the acute cases become subacute, the papules lose their redness, and become darker or somewhat livid or brownish in hue. At this point a high dilution of some drug which hastens desquamation may be added to the ointment or paste:

Zinc oxide		
Talcum	āā	10
Petrolatum		20
Rectified oil of birch tar		3

Label: Tar-zinc paste.

The use of tar preparations is indicated especially at this stage because of their effect in controlling dilatation of the blood vessels. They must be used carefully, however.

The above preparations are not to be used in cases of vesicular and moist or weeping eczema, in which the skin is in an even more irritable and intolerant condition. Impermeable substances, such as oil of silk or gutta percha tissue, should not be applied over wet dressings. It is distinctly desirable, however, to change the dressings frequently. Dressings saturated with any number of solutions meet the indications. Lead water diluted with from five to eight parts of water, solution of aluminum subacetate diluted with nine parts of water, and an aqueous solution of ichthyol 1:100, have proved efficacious. These solutions are best used cold, and should be changed every ten or fifteen minutes. Should there be no improvement from the use of these aqueous solutions or mild ointments, it is advisable to resort to the use of ointments or pastes of greater consistency; for example, zinc oxide ointment or Lassar's paste, applying the ointment on linen or mull bandage and swathing the part. If even thicker ointments and pastes do not bring results, it may be necessary to resort to energetic stimulation, which causes a crust to form. The crust acts as a protective covering under which the repair process goes forward. Stimulating applications may be made by painting the part with a 5 per cent. nitrate of silver solution, or with a 10 per cent. alcoholic solution of tar. After application the part is covered with starch powder.—EISENSTAEDT, in the *Journal of the American Medical Association.*

PROBLEMS OF BOARDING-OUT, WITH AN ATTEMPTED SOLUTION.*

BY HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

ONE of the most difficult problems in child-saving is concerned with the care of abandoned infants and little children. There are only two possible solutions of this question—either to collect the infants in institutions or to board them out. While institutions have somewhat improved their methods, the drift of opinion among those who know is strongly against the collective management of these cases, especially when the numbers are large. There has been an extraordinary agreement on this question among those who have had the widest chance for observation and experiment.

As far back as 1909 a conference on the care of dependent children was held at Washington, D. C., at the call of President Roosevelt, who was much interested in this vital human problem. A large number of practical workers and experts in child-saving from all parts of the country took part in the deliberations of this conference. Among many conclusions reached upon diverse problems of child-saving, the following especially concern us in this discussion: "Home life is the highest and finest product of civilization. It is the great molding force of mind and character. Children should not be deprived of it except for urgent and compelling reasons. . . . As to the children who for sufficient reasons must be removed from their own homes, or who have no homes, it is desirable that, if normal in mind or body, and not requiring special training, they should be cared for in families whenever practicable. The carefully selected foster home is for the normal child the best substitute for the natural home." We have thus represented in these words the national opinion on this subject.

Ten years later an international conference of Red Cross Societies held at Cannes gave what can fairly be said to represent the best world thought on this question as follows: "Permanent institutional care for infants and young children should be discouraged on account of the almost insuperable difficulties in maintaining nutrition in infancy under these conditions and because of the great susceptibility of young children to infection; preference should be given to placing such children in suitable families. All crêches, day nurseries and the like should be under close medical inspection."

As expert opinion is in such wide agreement upon stressing the family home rather than the institution in the care of the abandoned young, it is strange that more thought and effort have not been placed on the problems of boarding-out. The latter has not always functioned as well as it should, owing to lack of proper oversight and regulation. The old baby-farming experience, where an ignortant, careless woman, living in squalor, took as many babies to board as she could accommodate, with a sick and death rate rivaling the worst institution, at once comes to mind.

The two main difficulties of boarding-out consist, first, in selecting a suitable home, and next in exercising constant and proper supervision. Where boarding-out has fallen short, one or both of these factors have not been sufficiently emphasized.

In 1902 the writer developed what is known as the Speedwell System that represents a sustained effort so to regulate and systematize boarding-out as to place its good effects at a maximum and its possible bad effects at a minimum. This has been accomplished by developing what may be called a unit system of intensive boarding-out. A unit is a neighborhood that has been selected after a survey has been made to learn the general conditions of healthfulness and the number of good homes that may be available in the locality. There is then inaugurated a constant oversight, especially as to diet and hygiene, on the part of a salaried physician and nurse who are thoroughly familiar with this class of cases and competent to deal with them. The children are kept indefinitely, until digestion and assimilation have improved sufficiently to result in a permanent increase in weight and strength. Accordingly, work is kept up during the whole year and not limited to certain seasons. Efforts are made to train in each neighborhood a number of foster mothers, who, by natural aptitude under instruction and by constantly taking infants and young children into their homes, become fairly expert in handling them under conditions totally unlike those offered by institutions and far superior to them. We thus try to carry on an important educational work among the families taking our children. The constant oversight of our doctor and nurse is aimed to help each foster mother in the care of her own children as well. The homes in which the children are placed are to be helped finan-

cially by the board paid, and morally by the good advice and watching of the trained observers. Thus the simple machinery that endeavors to really and permanently help the abandoned and ailing child will, at the same time, assist in edu-

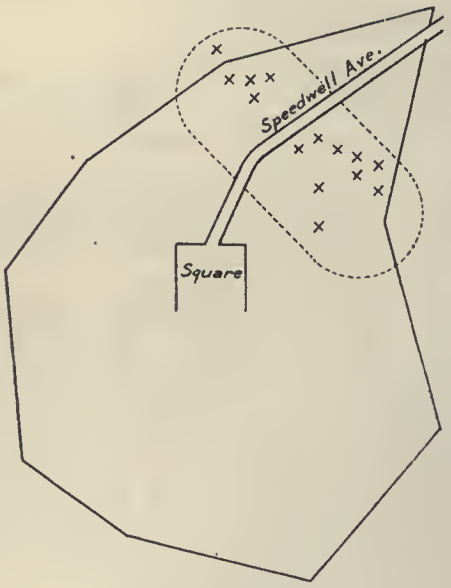

Fig. 1.—The Morristown unit.

cating each community in which it operates in prevention and care of its own ailing children. This by-product, involving improved social ideals and a higher standard of living, may be made a very important feature of this work. It need hardly be stated that this individual and social ideal, in order to attain its highest success, must be operated by those who believe in it and are willing to put forth enthusiastic efforts toward its support. In other words, the human effort is here

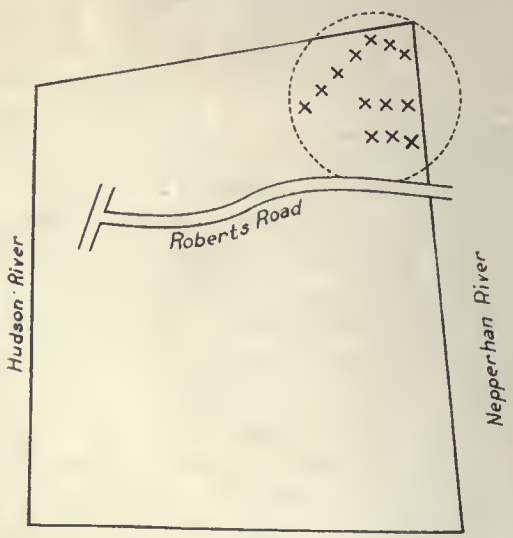

Fig. 2.—The Yonkers unit.

the important factor, and the system in order to attain its greatest efficiency calls for high-grade workers who can idealize their efforts and for good family homes where the boarded-out children will be reared under constant and intelligent supervision. The emphasis is thus placed on *human agents* rather than on bricks and mortar.

The underlying idea of a unit is to comprise a certain area in city or country, that will be sufficiently circumscribed to allow the workers to be acquainted with the personnel of a neighborhood and accessible for communication. It may include a part or whole of a village, or a ward in a city.

The formation of a unit involves first the picking out of a number of promising homes after the preliminary survey. Our experience has shown that it is a mistake to be too fastidious in selecting the homes. If the woman of the household has motherly instincts and fairly healthy children of her own, and seems teachable, a certain amount of dirt and disorder can well be overlooked at the start. A porch or back yard, or some open space, is essential, as plenty of fresh air is one of the most important features of this work.

The next step is to select a committee of women

Fig. 3.—An uncovered porch, a kitchen chair, a basket and a towel to shade it; one of our best plants.

living in or near the locality selected for the unit, who are familiar with the neighborhood and the people, and who constitute the local managers of the undertaking. They help in raising money and supplies, assist in friendly visiting in the homes, acquaint themselves with neighborhood conditions and in these and other ways exercise general supervision of the work.

The records kept of the children are uniform in all the units and careful histories on a card system show the conditions and results of their care.

The following card blank is used for this purpose:

SPEEDWELL SOCIETY.

(——— X Unit)

Name	Sex.	Age.	Received from.
Date of arrival.	Weight when received.		Weight when discharged.
Previous history.			
Present condition.			
Diagnosis.			
Food and treatment when received.			
Treatment.	Boarded with.		

Our experience shows it to be a mistake to try and keep too elaborate and complicated a system of histories. The object in this work is not research but helpfulness to the children, and not many data are required for this purpose.

Fig. 4.—The upper figure is that of an infant three months old weighing 5 lb. 12 oz. The lower figure shows the same infant returned after ten months, weighing 25 lb.

In comparing the results of institutional care with systematized boarding-out, it will be found that both mortality and morbidity are less under the latter plan. The mortality in institutions as elsewhere, is greater the younger the infant and hence published statistics should always be rendered at intervals of six months in order to have a true interpretation of existing conditions.

The reports of the New York State Board of Charities for the years 1914 to 1918 show that 14,525 children under two years were discharged from institutions in the State. Of that number 6583 were deaths. Of 12,437 little children who on the date of separation from the institution had been there one year or less, 6503 died. It should be noted that these figures do not include hospitals for acute cases of illness. In New York it was found that during four years the death rate of infants under two years of age through the State was only one-fifth that of children in institutions included in the same area.*

Aside from the large death rate there is a large morbidity in the institution, largely due to atrophy and to the many forms of contact infection. It seems impossible to avoid manifold cross infections when these susceptible infants are handled in mass. Their mucus membranes soon show a low resistance with resulting catarrhal inflammations that are difficult to control. All kinds of colds, especially of the influenza type, run unchecked, and many cases of bronchitis, bronchopneumonia, otitis media and subacute vaginitis are thus explained. All these factors result in the devitalized babies so often seen in institutions. Many of these dangers are avoided in a properly regulated boarding-out system.

Not only has our death rate been low, but there has been little sickness, especially of the communicable variety. A certain amount of illness is unavoidable, particularly among children of this type, but communicable diseases and cross infections that abound in institutions are usually a direct *result* of the environment. This danger is largely avoided in the Speedwell plan. As an example, 1,094 children were received and treated in a little over five consecutive years. Their stay in the boarding-homes varied from a few weeks to several months, with an average of about four months. During these years, and among this large number of children, only twenty-one cases of communicable disease occurred, as follows: Seven cases of chickenpox, seven cases of whooping-cough, three cases of measles, one case of Liberty measles, two cases of diphtheria—one nasal and one only bacterial—and one case of scarlet fever. These cases were nearly all in the stage of incubation when sent out, so that the disease was not contracted owing to the operation of the system. Two cases of chicken-pox and one of whooping-cough were contracted in the boarding-homes. As far as can be learned, few, if any, of the local children have been infected by our cases. We know of no other plan that could handle such a large number of children of this type with so little spread of infection.

Fig. 5.—The upper picture is that of an infant 5 months old, weighing 8 lb. 5 oz. The lower picture shows the same child returned after eleven months, now weighing 26 lb.

The results for 1919 in the two units directly operated by the Speedwell Society are as follows:

*Transactions American Association for Study and Prevention of Infant Mortality, 1914.

Morristown Unit (From November 30, 1918, to December 31, 1919).

	Admitted.	Discharged* Improved.	Discharged Unimproved.	Died.
Under 6 months	15	13	..	2
6 to 12 months	3	3	..	..
12 to 18 months	8	8	..	..
18 months to 2 years	9	9	..	..
2 to 5 years	79	79	..	..
Over 5 years	58	58	..	..
Total	172	170	..	2

*Twenty-three still in care and soon to be discharged: are all gaining.

Yonkers Unit (From January 1, 1919, to December 31, 1919).

	Admitted.	Discharged Improved.	Discharged Unimproved.	Died.	Remaining January 1, 1920.
Under 6 months	22	12	2	3	5
6 to 12 months	20	15	3	....	2
12 to 18 months	7	7	....	....	.....
18 months to 2 years	11	6	....	1	4
2 to 5 years	18	17	....	....	1
Over 5 years	6	6	....	....	.....
Total	84	63	5	4	12

In order to consider a case improved, before or at discharge, there must be a gain in weight and better appearance and vitality.

After considerable experience we have found that this method of operation is not adapted to handling cases of acute sickness that are best managed in a hospital.

In the earlier years of experiment all kinds of cases were sent out to the boarding homes, such as acute toxic infections, unresolved pneumonias, and, in the summer months many babies who were near death from bowel disturbances, in the hope that change and fresh air would give them a chance. This gave a hospital mortality. Besides, the foster mothers became fatigued and discouraged and did not possess the necessary nursing skill or appliances. After acute disease has subsided, however, the results in rapid convalescence have been most satisfactory. It is rarely possible

Fig. 6.—The child seen in the left-hand picture was 16 months old and weighed 14 lb. 12 oz. On the right is seen the same child returned after four months, weighing 23 lb.

for an infant or young child to get strong in a hospital. If kept too long, recurrences of the original disease frequently happen from auto- or hetero-infection. The results in those difficult cases of wasting, or atrophic infants, taken from institutions or tenement houses, have been most encouraging. In the institution these babies lie for hours unattended, and especially at night receive insufficient care. They need to be handled more, to be occasionally carried about, and to receive

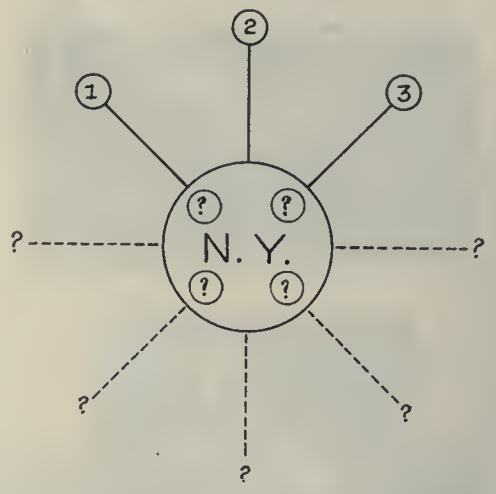

Fig. 7.—Diagram showing the three units thus far developed by the Speedwell; these are at Morristown, N. J., and Yonkers and New Rochelle, N. Y.

more fresh air. A little personal loving attention also has a therapeutic value.

Finally, the children have nearly always left our care in good physical and mental condition, such as would be apt to follow a more or less prolonged stay in a natural home. Too much praise cannot be given to some of our foster mothers who have done splendid work. They have recreated many a weak and ailing child who would otherwise have dragged out a feeble and inefficient existence.

The daily per capita cost for 1919 was $1.23 for the Morristown unit and $1.20 for the Yonkers unit. This is obtained by dividing the total number of days service into the total cost of operation. It includes traveling expenses of nurse and child to and from the country, extra clothing, special milk, the price of board and salary of doctor and nurse, with occasional unforeseen additional expenses. The cost for 1920 will be higher.

It is becoming increasingly difficult to secure good boarding homes for little babies, especially those of the atrophic type. They require constant care, night as well as day, and are liable to die in spite of all that can be done for them. There should be a sliding scale of prices, paying women who take such cases a much larger sum than is usually allowed. A system of prizes might also be offered for the successful handling of these little babies. We now give $18 a month and in addition pay for the best grade of milk, but this payment must still be increased if necessary to hold women on this important job.

If the lives of these little waifs are worth anything, they are worth much more than is usually paid to try and save them. It must be remembered that in the boarding-out plan there is no interest on invested capital, no overhead expense in running a plant, and no remitted taxes to be counted in the cost. If the large institutions will sell their expensive plants and use the money in

intensive human service, i. e. in paying doctors and nurses, with more generous treatment of foster mothers, this problem would be in the way of solution. A striking comparison between institutional and boarding-out mortality, as influenced by care and cost, is afforded by the results obtained by the Sage Foundation and Dr. Baker of the Department of Health, taken from the marasmus ward of a large infant's institution.* This ward receives only the chronic cases of extreme atrophy that have always resulted in death. In boarding out a number of these babies, an extra bonus per month was given to selected women. and a doctor and a nurse were furnished to every ten babies. There was an eventual mortality of 46 per cent. Thus nearly half of the babies were saved by special treatment in the homes, who were bound to die in the institution. We must note the way this boarding-out was done. Constant supervision and intensive working produced these brilliant results. There is no reason why such operation could not be continued on a large scale.

A few small plants could serve as collecting stations which would be all that would be necessary from the institutional standpoint when operating this form of regulated boarding-out. This would not only result in a great lessening of devitalized babies but would let loose educational and social propaganda whose effects would be widespread and beneficial.

These babies are not having a fair deal. Let us try and give them natural and watchful care in the way they need. They are brought into the world singly, not in droves, and they suffer in the crowd. We often hear the old adage, "Eternal vigilance is the price of liberty." Let us paraphrase it and say, "Eternal watchfulness is the price of life," as far as the weak, abandoned baby is concerned. We believe the plan sketched in this paper affords the most practical method of watching and saving these babies. We would like to see every large city develop this work according to the scheme shown in the following diagram. This would consist of various collecting units in the city that would be in constant communication with units in the surrounding villages. Thus far the Speedwell has developed three of these units, one at Morristown, one at Yonkers and one at New Rochelle that is operated by the Free Synagogue for the care of Jewish children in preparation for adoption.

51 West Fifty-first Street.

Woman's Medical Journal, January, 1916.

WEAKENED FOOT: ITS MEASUREMENT AND CORRECTION.

By CHARLES PELTON HUTCHINS, M.D.,

SYRACUSE, N. Y.

FORMERLY MAJOR MEDICAL CORPS, AND DIRECTOR OF PHYSIOTHERAPY, U. S. ARMY GENERAL HOSPITAL NO. 28, FORT SHERIDAN, ILLINOIS.

Weakened foot represents an adynamic condition, giving rise to varying degrees of disability or deformity or both. "All degrees occur from slight strain of the ligaments and tendons by which the arch is maintained, to complete descent of the arch with osseous deformity." It is evident, therefore, that weakened foot would never occur under proper conditions maintained by proper use.

The overwhelming predominance of weakened foot with resultant deformity to some degree of pes planus uncovered by the draft examinations leaves

Fig. 1.—Represents the location and indicates the specific action of the supinators-tibialis anticus and posticus, and the main accessory—flexor longus hallucis. The illustration serves to demonstrate that the anticus is the supinator in dorsal flexion of the foot, and the posticus in plantar flexion. The passage of the hallucis under the sustentaculum tali aids in supporting the anterior end of the calcaneus. Weakness of these muscles is the first step in weakened foot.

little to speculation that the man power of the country is materially affected thereby. "The condition was found in the ratio of 177.45 per thousand, or nearly eight times as frequent as any other defect."

There is, according to the Munson Board, "no dispute over the primary cause of flat foot; the structures are not sufficiently strong to support it." *Structures* refers to the soft parts; and their agency in the maintenance of foot integrity is commensurate with their physiological competence. To quote further from the findings of the Munson Board, "if pressure from above is greater than the tension exerted by the elastic muscles below, the excess pressure falls directly on the ligaments of the foot." This results from either increased body weight or weakness of muscles. As long as muscle tone and tension is commensurate with the superimposed weight; as long as the muscles are guarded from fatigue and overstretching; as long

Fig. 2.—Lower segment shows the bony structure of the lateral arch; the part of the foot receiving the weight in walking, and carrying the brunt in the passive four square position. Upper segment (the tangent) delivers the thrust for the succeeding step. Alterations in the bony relations begin in the posterior arm of the lower segment, turning the exposed facet inward and downward.

as they function in ordained lines unmodified by improper shoes, tender points, or toeing out, equilibrium will sustain the component parts in proper relation.

Studies in causes and results in pes planus have

brought the conviction, that whatever the original cause of disuse in any part, contractility and elasticity of fibroelastic elements have become affected and the reciprocal relation disturbed.

Machinery of the Foot.—The tissues that compose the foot and their general anatomical relations are so well understood as to preclude the necessity for a detailed review. A study of the values of the components, the distribution of force, the behavior of the segments in meeting that force, and the selective functions of the several parts in the performance of the act of walking has, however, an intimate relation to the disabilities and subsequent, if not consequent, deformities to which the foot is prone. For it has been generally observed that sooner or later the weakened foot develops symptoms and malposition.

FIG. 3.—Radiograph of antero-posterior view of normal foot (left) (Case 6149) without weight bearing. CD defines the weight bearing (Meyer's) line, depicted by lead wire strapped on anterior surface of leg. AB shows lead wire strapped vertically to posterior surface of heel as near the center of calcaneus as can be estimated from surface markings. The decipherable outlines of calcaneus, astragalus and scaphoid are indicated by dotted lines.

The foot is a complex structure; it is more, it is a complex mechanism. In an analysis of the foot as a functioning organ, an enumeration of muscles, ligaments, and bones brings out certain patent facts, which are generally accepted. The structure and shape of each bone, the arrangement of the laminæ, the facets clearly evidencing the direction and extent of the joint motion, the tubercles, prominent ridges, and the gradual tapering of the bony structure from calcaneal tuberosity to phalanges show plainly the part each is to play as an individual in the piece.

The foot is a lever of the third order. The weight lies between the power and the fulcrum. This applies, of course, to the walking or active foot, which is the one under discussion. It is a double-action third order lever. The act of walking embodies two distinct performances; the body weight is received upon the forward foot and

FIG. 4.—Identical with Fig. 3 in position, but with weight bearing. Note the black line of lead tape near C. Rotation of heel under weight bearing is not present, as the relation of lines AB and CD is unchanged in the normal foot.

brought to a point where the center of gravity of the body is over the intermalleolal line; the second action begins at that juncture, consists in deliver-

FIG. 5.—Lateral view of normal foot. AC is drawn from inferior border of heel to head of fifth metatarsal; CD from same point to lower border of anterior part of calcaneus. The angle at C represents the obliquity of the posterior arm of the lateral longitudinal arch. B is the posterior margin of the fifth metatarsal.

ing the body weight forward, and terminates when the foot leaves the ground. In the performance of the receiving functions, the fulcrum is at the heel and the power is supplied by the dorsal flexors (Fig. 1); in accomplishing the forward

thrust of the body, the fulcrum is at the head of the first metatarsal and the power is exerted through the tendo Achillis. Let us follow the transferrence of weight along the bony framework. From the tuberosity on the plantar surface of the calcaneus posteriorly, part of the weight moves along the "lateral longitudinal arch," to use the designation of Lewis, through the cuboid to the fourth and fifth metatarsals. Lewis pertinently calls attention to the calcaneocuboid joint, which, he says, "possesses a special mechanism for locking and allows only a limited motion. The most marked features of this arch are its solidity and its slight elevation." From this point the weight to be borne by the anterior lever is diffused to the heads of all the metatarsals and the point of equilibrium is reached. In advancing for the next step, such weight as the calcaneus bore is transferred along the lateral arch and the whole accumulates at the inner half of the anterior metatarsal arch and is transmitted therefrom through the first, second, and third metatarsals, the cuneiforms, navicular, and talus to the tibia. The calcaneus carries the power and not the weight.

Fig. 6.—Without moving the foot in the slightest from Fig. 5, weight bearing was assumed. Note here again that the secondary change of depression of anterior end of calcaneus is not present, and that the angle at C remains the same.

Fig. 7.—Case 5177. Fourth degree planus. Without weight bearing. Line AB (vertical marker on heel) not quite parallel to Meyer's line (CD). This is due to extreme relaxation of fibro-elastic structures and demonstrates that bony relations are not reestablished on removal of weight.

Fig. 8.—Case 5177. With weight bearing. Note divergence of AB, revealing pronounced external rotation of calcaneus. Deformity has progressed so far as to curve Meyer's line in eversion from the subastragaloid joint down.

It is evident, then, that the physiological division of the internal set of bones from the external set, as Davis puts it, separates the third and fourth metatarsals, the external cuneiform and cuboid, and the talus and calcaneus. Quinn and Kuss have a more fanciful than rational concept of the internal segment as furnishing support and the external segment balance. Where else in the skeleton, I would inquire, do bones and joints mislead in their compensating attributes of strength and motility? Is it not wholly logical to liken the lateral arch to the lumbar spine and the median arch to the cervical?

From the mechanical standpoint it is illuminating to consider the astragalus, navicular, the three cuneiforms, and their articulating metatarsals as forming a tangent to the lateral arch and resting by an offset on the vertex of that arch (Fig. 2). This harmonizes with weight transferrence and with the subdivisions of the mechanical processes. It is of small moment as a topic of argument, but vital to the estimation of comparative values of fundamental and accessory parts in beginning dysfunction. And on the mus-

cular side muscle sense represents the accurate grading of motor impulse and therefore stimulates contraction in proportion to the work to be accomplished. There is rarely any damage done to muscle under this impulse; it rather makes for increased strength and power to perform. Suspend muscle sense or let it fail to measure up to the demand from weakness or other cause when interposed between bodies whose impact force is a fixed quantity, and overstrain will inevitably result. This situation develops only as the foot receives the load. In delivering it, on the other hand, the muscle acts within its ability to discharge the motor impulse. Since it is patent there will be no driving force without muscle tension, the tangent itself is safeguarded in shifting its load far more positively than is the fundamental arch in coping with what is thrust upon it. Compare the power of the combined contraction of the gastrocnemius, soleus, tibialis posticus, flexor longus hallucis and digitorum, and peroneus longus acting on propulsion with the comparatively weak action of the muscles of the anterior aspect gradually relaxing as the foot receives the weight. That the strongly constituted external border of the foot depends to a lesser extent on muscular support, the powerful inverters—anticus and posticus—attached to the most effective point of the tangent find no counterpart in the peronei tertius and brevis.

Fig. 9.—Case 5177. Under correction by Rotameter with weight bearing. The relations of bony parts as to eversion have been restored by internally rotating the os calcis, bringing that bone into fair relation to Meyer's line. AB is brought parallel, but is carried outward by rotation of the heel.

Fig. 10.—Case 5177. Lateral view; without weight bearing. Shows secondary effect by depression of anterior end of os calcis. Compare angle at C with Fig. 5.

Fig. 11.—Case 5177. With weight bearing. Angle at C further reduced with noticeable lowering of tangent; lateral interpretation of Fig. 8.

Much stress is wont to be laid on the ligaments in preserving the contour and function of the foot. Valuable adjuncts, as they are, in maintaining articular facets in apposition, they are inelastic structures and will ultimately yield. Were it not for the ligamentous action of muscles, sprains with their sudden solution in continuity of ligament would be as ubiquitous as the autumn leaves. Reduce this muscle support ever so little and repeat the resultant strain on ligaments the myriad times the foot is challenged to accept its inexorable burden, and the ligaments will be found to have sagged pari passu with muscle incompetence. "Muscle tension and balance thus maintain the foot arch in its proper curvature. Where this is lost, the arch tends to flatten. . ." (Soldier's Foot.)

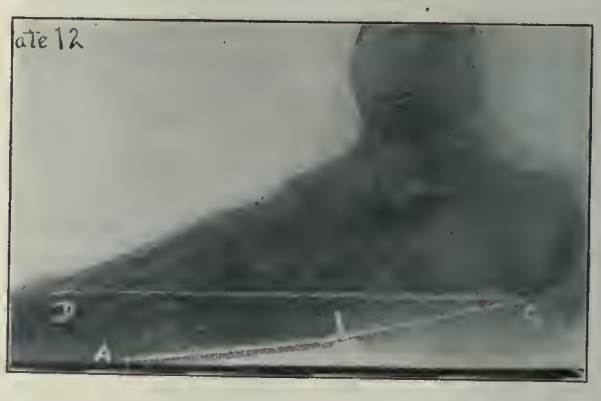

Fig. 12.—Case 5177. Under correction, as in Fig. 9. Of especial interest is the elevation of the navicular above line CD, as compared with Fig. 11.

Dysfunction.—The spread of the heads of the metatarsals with their toes checks the tendency of the calcaneus to rotate. The calcaneus, however, has had free opportunity to so rotate before the anterior part of the foot comes to the ground. In the first place the fact that it lies slightly external to the line of weight-bearing and receives the full load with no assistance in the preservation of its perpendicularity save the tibiales and flexor longus hallucis and what postural advantage the four-square placing of the foot on the ground affords, presents a predisposition to external rotation with the advent of any abnormal-

Fig. 13.—Case 4151. Gun-shot wound that punched out cuboid. Without weight-bearing radiographic relations shown to be excellent.

ity of the contributing supports. Secondly, the preachment for generations has been for the fallacy of turning the toes out, and the walking is so "done with an everted foot, the less the body is supported by the strong outer portion of the foot and the more the body weight is thrown upon the weak inner portion, *not intended to support it.*" (The Soldier's Foot). This is potential flat foot.

Displacement of the bones of the tangent supervenes readily and with increasing ease as the calcaneus rolls out from under the talus. The astragalus resting now on an incline slips downward and inward, carrying with it all the bones of the inner border and producing actual pronation. Flattened foot is, therefore, a change in structure resulting from the inability of the muscles of inversion to perform their assigned function in the

Fig. 14.—Case 4151. Although wound had been healed many months, disability was complete and crutches necessary. Much persuasion was required to secure weight bearing for the exposures because of pain. Effect of angulation produced by muscle tension to resist pain.

support of body weight. It is apparent, then, that when disability and deformity supervene, the earliest malposition must take place in the lateral arch and not in the superimposed tangent.

Predisposing causes are in the main occupational; vicariously occupational at that. Seden-

Fig. 15.—Case 4151. Lateral view without weight. Complete crippling with no disturbance of the median arch.

tary pursuits, vehicular travel, the substitution of social games for athletic, and the whole gamut of step-saving devices conspire to muscle weakness and fat accumulation. Compared with these elements of physical neglect that filch the vitality

of all tissues devoted to locomotion, modish dress with its high heels and pointed toes appears trivial. It is axiomatic that use predisposes to increased ability to perform, and conversely, that disuse predisposes to atony and atrophy.

In the course of restoring functions to lower

Fig. 16.—Case 4151. With weight. Anterior end of os calcis dropped from loss of keystone of lateral arch (cuboid); shown by acute angle at C.

extremities of wounded soldiers consequent to peripheral nerve injuries, their surgical repair, and incidental immobilization, it was apparent that many cases of weakened foot were developing. This complication necessarily developed

Fig. 17.—Case 4544. Without weight. Double trench foot, necessitating amputation of heads of first and second metatarsals. Normal relations with os calcis marker parallel to Meyer's line.

from the active use of the leg in the resumption of walking. The policy of encouraging men with drop-foot to walk with the dorsal support could not but tend to external rotation of the calcaneus, bereft of the assistance of the tibialis anticus and its homologues. The wrapped legging and snug puttee are favorable to the incurrence of weakened foot. Circular pressure on a limb interferes with nutrition and restricts the full bellying of muscles in contraction. It contributes to loss of tone and atrophy.

Fig. 18.—Case 4544. With weight bearing. Slight rotation from attempt to balance without heads of inner metatarsals. No discomfort; only disability occasioned by loss of pushing power of great toe.

Just after the conclusions had been reached that the median longitudinal arch depended for its integrity upon the preservation of the lateral arch, two cases presented themselves to the Department of Physiotherapy at Fort Sheridan. The

Fig. 19.—Case 4544. Without weight. Normal relations, although there is no completion of the tangent: therefore no so-called "arch."

one, Pvt. O. G., had a double amputation of the metatarsus, the result of "trench foot." The line of amputation ran from the head of the fourth metatarsal to the middle of the shaft of the first metatarsal. The anterior arm of the median line

of bones was ½ inch off the ground in weight bearing, eliminating any function of the inner border. There was no pain on standing or walking. Dysfunction did not exist in receiving the body weight on the foot, but there was no ability

FIG. 20.—Case 4544. No change from Fig. 19 under weight. Able demonstration that lateral arch maintains contour of foot.

to thrust the body forward; which, it is contended, is the purpose of the tangent. (See Case 4544).

Case 4151, on the contrary, had a perfectly normal median arch as to contour and flexibility. A piece of high explosive had punched out the cuboid, breaking the continuity of the lateral arch and, so far as that arch was concerned, leaving the calcaneus unsupported anteriorly. The slightest attempt at weight bearing occasioned excruciating pain at the taloscaphoid articulation. Notwithstanding, therefore, a perfectly preserved inner border, the calcaneus, unsupported by the cuboid, was unable to receive the weight of the body or a fraction of it. The patient was still on crutches, though the wound had healed months before and, realizing that efforts at relief had been vain, was urging amputation. (It might be of interest to know that the orthopedic service was considering as a preliminary procedure an arthrodesis by bone graft between the calcaneus and fifth metatarsal.)

If exciting causes are those which promptly produce symptoms, in weakened foot the line of demarcation between predisposing and exciting causes cannot be sharply drawn. When enfeebled muscles throw excessive burden upon ligaments, discomfort will result. Distinction must be made between deformity and disability. While symptoms usually occur before the deformity is apparent to the patient, they are in no respect a measure of it. And it is this class of disabled cases that appeal for relief. The strain, the obliquity, and the descent are sometimes so gradual that planus results without disconcerting pain, although "observation and study of this class of cases compel the conclusion that every case of flat foot does give symptoms sooner or later, if subjected to intensive training." (*Military Surgeon*, Jan., 1918.) Out of 2,000 cases examined by the investigator just quoted, 600 were pronated to the first, second, or third degree; and of these 60 per cent had no symptoms. Physiological pronation produces disability, whereas anatomical pronation spells deformity, whether it is disabling or not.

Estimation of Deformity.—The issues that must be taken with published findings on foot abnormality are the inadequacy and mechanical inaccuracy of (1) measuring deformity by soft tissue prints; (2) roentgenological estimation in lateral position of bone displacements of the passive foot; and (3) casting the non-weight bearing foot for correction and shoe requirement.

"Degree, as determined by foot imprints alone is not especially definite or positive." (Gosman and Perry.) Soft tissue prints obscure results by the variation in adipose tissue and, in any event, register secondary changes only. This latter criticism applies equally well to *x*-Ray findings in the lateral position, even in weight bearing, so far as the depression of the anterior end of the calcaneus and the subsequent lowering of the talus and navicular are concerned; without weight bearing the finding is deceptive from disregard of elastic elements. Of the third method referred to above it is sufficient to call attention to another conclusion of the Army Board that developed the best shoe ever issued to a soldier: "While shoe fittings in civil life are habitually based on feet at rest and thus occupying the minimum space in the horizontal plane, the method of shoe fitting here described is based upon the fact that the foot in action differs very materially in appearance and dimension from the foot at rest . . ." The elastic content of muscle and ligament tends to return the bones of the tarsus to their normal relation when weight is removed. Therefore, estimate of the deformity can be made only when measurement is made in the weight bearing position.

Bradford as late as November, 1919 (*Journal of Industrial Hygiene*, p. 351) said "a plaster-of-paris cast is unnecessary and may be misleading since it gives only the contour of the feet at rest and not in action." And the best advice he could offer

FIG. 21.—Case 3747. Illustrating internal rotation by the rotameter to normal inversion. Elevation of inner border being measured for amount of lift required on correction plate.

to the physician for the estimation of foot defects was to "watch the gait of the individual," and to take the time-worn imprint of soft parts in the static position.

Plasticity of the foot is a prerequisite to cor-

rection. Rigidity is a complication that must be overcome before the foot is amenable to postural correction of the overstrain that occasions pain and deformity. A simple test of flaccidity is to seat the patient and so place the foot on Bristol

Fig. 22.—Cast moulded to active foot with eversion corrected. Mould is poured into undisturbed cast.

board dusted with talcum that the lower leg is vertical. Require the patient to advance the foot as far forward as possible, keeping the ball of the foot touching the board. The tension on the tibialis anticus in a well advanced position will draw up the inner border to a well-developed arch in any foot that is not rigid.

To mark the behavior of the calcaneus under weight bearing and to depict its rotation rontgenologically required facilities and a technique that U. S. Army General Hospital No. 28 supplied. Through the scholarly and earnest cooperation of Major H. G. Maul, M.C., Chief of the *x*-Ray laboratory, a technique was evolved that brought to light the primary changes in the long axis of the foot from unsustained pressure. An uniform procedure was adhered to. The exposure was anteroposterior. The patient was seated with the foot touching but not resting on the pedestal. Meyer's line was marked by a lead wire taped on the anterior surface of the leg, and a vertical lead strip was centered accurately on the posterior surface of the heel. The tube was placed 28 inches from the plate, which was vertical, against the heel and projected 4 inches below the sole of the foot. The ray was centered at the talotibial articulation and with a 5 inch gap and at 30 milliamperes, exposure was for 7 seconds.

Without changing the position of the machine or foot, the patient was assisted to the standing position and required to distribute weight equally on both feet. This exposure registered the changes produced by weight bearing. For the third exposure—that of corrected posture—the calcaneus was internally rotated by a lever operated by a screw until the gross appearance of the foot showed that adequate supination had been restored. Reference to Figs. 3 and 4 of the normal foot, show almost no rotation to the calcaneus under weight bearing. (Correction was not used in the control plates.) On the contrary, the obliquity of the heel marker to Meyer's line in Fig. 8 and even the curving of the line itself from extreme pronation, is easily decipherable. Case 5177, being a fourth degree type, is not susceptible of complete correction and the heel marker is not perfectly vertical.

The necessity for employing the active (weight bearing) foot in the estimation of the amount of external rotation of the calcaneus, and the amount of postural internal rotation required to correct it, is evident. For all intents and purposes the trained eye finds no difficulty in judging the requisite amount of heel inversion. To put it graphically, the external promontory of the tubercle of the os calcis should line anteroposteriorly with the lower border of the external surface of the trochlear of the talus. (See Figs. 21 and 22). These can readily be identified on the surface.

Studies were also made in the lateral position in quest of data that might lead to surface interpretations of the amount of downward displacement of the anterior end of the calcaneus. The change in technique for the lateral exposure including placing the tube horizontal, centering on the calcaneocuboid articulation, and reducing the exposure to three seconds. Comparison of the length of AB and BC (Figs. 5 and 10) in a group of cases revealed that AB is normally longer than BC; that when BC is greater than AB a condition of advanced pronation exists; that a fairly accurate determination of the comparative length can be made from the surface markings. In twelve cases with no foot record, selected at random in wards, it was found that in eight AB was greater than BC; in two (one a negro) AB equalled BC; in two (both with symptoms of weakened foot) AB was less than BC. (See Figs. 6 and 11).

The Rotameter.—This instrument is a platform whose floor plan fits the feet in the four-square position. The outer sides have a curb moulded to the outer border of the foot with an offset to avoid

Fig. 23.—Correction plate made for Case 5177. Note lift of 5/16 inches to reproduce correction by the rotameter.

pressure on the base of the fifth metatarsal. The heels rest on plates 2½ inches square inlaid in the base and hinged at the angle of the curb. Thumb screws operated from beneath bear upon these plates. A solid post carrying an adjustable cross

arm at the level of the inner (subcutaneous) surface of the talus stands midway between the inner malleoli. Placed on a table with the patient standing thereon steadied by a support chest-high, the operator can with accuracy and despatch determine, by plumb line (except in genu varus and valgus) and the surface anatomical points described above, if rotation exists.

The prerequisite of a device that will measure the amount of rotation of the os calcis is the fixation of the anterior metatarsal line to the weight bearing surface. The torsion of the foot normally maintained by the supinator group is disturbed when the subastragaloid joint has yielded and pronation begun. Before inverting the calcaneus, therefore, the ball of the foot is snugly secured to the platform by a transverse strap. A proposed correction that allows elevation of the inner border of the sole takes no cognizance of foot elasticity.

Correction, which means readjustment of deformity where it begins, is accomplished by turns of the screw until the designated points on the calcaneus and talus line up. The outer border of the heel is firmly held in the angle of the curb and the weight bearing line falls without the line of support. (Fig. 21). The elevation of the inner border of the heel is the amount of lift to be added to the correction plate.

The Mould.—With the ball of the foot still secured and the incline in its registered position, the heel is raised and twelve thicknesses of plaster bouillon gauze is slid under the foot to the tarsometatarsal joint. Weight bearing in the same position is resumed and the plaster moulded to the top of the fatty cushion on the outer side and just below the inner malleolus. Counter pressure on the plaster over the astragalus by the cross arm establishes a moderate leverage to preclude further strain on the subastragaloid joint and obviate any possible play between foot and plate in walking, which is the element of failure of the Thomas heel (Fig. 22). As soon as the plaster is set, the patient is released by carefully sliding the foot forward, leaving the undisturbed mould of the corrected weight bearing foot. The usual procedure of coating the skin with vaseline in plaster work is to be observed. One would wish to afford the patient a more comfortable position, but thorough preparation reduces the manipulation to a few minutes and no intolerance has been manifested even by female subjects.

The Cast.—Into the unhandled mould plaster grout is poured after the Whitman method. Similarly, too, when this in turn has set, it is delivered from the mould, smoothed and polished with talcum, the outline of the proposed support inscribed on it with the name of the patient, and the degree of angle of inversion on which it was cast. (Fig. 23).

Gosman and Perry's conclusion that "we are convinced that any form of artificial support to any arch is decidedly detrimental" (*Military Surgeon*, Jan., 1918) is to the point. It is consonant with the findings of this paper and with the pathology this heel support is designed to aid in rectifying. Aid is used advisedly, for treatment must consist in both alleviation and redemption.

Weakness of the supinator muscles is the primary etiological factor, and in the redemption of the supinators lies the hope of cure. As pronation develops, the tibiales muscles (disregarding for the moment the effect on other tissues) become overstretched from lowering of the points of insertion, which decreases their contractile power and tends to further deformity in active use. In order that this may be prevented during the period of muscular redevelopment, it is essential that the points of insertion be held to proper elevation by mechanical means that will operate to reduce the deformity at the point of origin—the calcaneus. The Thomas heel, it has been already conceded, had a similar motive, which failed of fulfilment in the majority of cases that have come to the writer's attention, because of the rotation of the foot within the shoe and the subsequent overriding of the outer counter. In like manner and for the same reason insole leather wedges of the so-called "tomahawk" type have been disappointing. "Arch supports" are beyond the pale and as unworthy of serious notice as of public confidence.

The rotating support pictured in Fig. 23 is a perfect fitting of the *active* foot by accurate measurement of required inversion. Its mechanical action is one of internal rotation of the calcaneus and restraint of the astragalus from further slipping inward and downward from its perch on the crest of the lateral arch. The calcaneus does not at any time in the act of walking escape from its grip and the supinators, relieved from overstretching, are preserved during the periods of relaxation in a position essential to reacquirement of power and tone. The secondary effect on the bones of the foot as a whole is to restore, by the torsion occasioned by walking, the midtarsal arch by elevating the upper end of the tangent, when the head of the first metatarsal is the fulcrum in delivering the load. No constriction is made upon soft tissues, save that transmitted through the os calcis; no element of the vicious plantar crutch is exerted by it.

Contour, posture, and power to perform are the trinity in foot function and the greatest of these is the last, for on it hangs the burden of the other two. It has been postulated that the foot in question is flaccid; that any rigidity due to long continued strain, or any spastic type from peroneal spasm, has been first converted into flaccidity. For the rigid foot has developed from involuntary muscular immobilization to give relief from pain produced at the periosteal attachment of ligaments following bony displacement.

When a period of rest from active weight bearing is urgent as a preliminary measure in pronounced cases of periosteal pain, and in the presence of tender points, as callosities from the use of unnatural pressure points, daily massage and passive motion with special emphasis on dorsal flexion will stimulate circulation and hasten tissue regeneration. In direct proportion to the degree of pronation, the peroneal group shortens in conformity with the natural behavior of opponent muscles. The peroneal pronator group must of necessity, then, receive the full measure of manipulative attention to prevent not only their restraint of tibial contractility, but also to reduce

tension upon the supinators during periods of rest in equilibrium. Proper massage at this time will obviate the necessity for fixation.

The kind of exercise to be selected to effect redemption and its manner of performance is of the utmost importance. Ordinary walking with the inverting support overcoming strain may be all that the patient, now relieved, can be induced to take. The conclusion of Gosman and Perry from their thorough study in reclaiming the soldier's foot, that the "non-resistant exercise plan is most effective" is generally concurred in by authorities in physical training. These authors outline a facile and effective scheme of graduated exercise, as follows:

1. With the toes projecting over the edge of the pedestal (a 2 x 12 inch plank, for instance) steady and firm contraction of the accessory flexor longus hallucis and flexor longus digitorum is practised slowly, relaxing easily between contractions.

2. Push the same exercise with greater effort until the tibialis anticus joins in the action, giving the foot the appearance of a half-closed hand. Relaxation between contractions must be slow and complete. The exercises are to be so graded, as to stop short of fatigue.

3. Emphasis is placed on walking with toes straight forward.

Many combinations of these essential actions may be devised or utilized, if one so wishes, without sacrificing the ultimate aim.

As Colin Mackenzie has specifically indicated, in harmony with muscle action, the flexors of the toes have no action on the ankle or tarsal joints; its support of the sustentaculum tali, however, makes the hallucis the most important accessory supinator. Again, joint motion must be unrestricted for the proper play of muscles acting upon and over the joint. It is well to remember in the selection of shoes, therefore, that the toes are to be allowed free movement, not only as a matter of comfort, but for the untrammeled action of the flexor longus hallucis and flexor longus digitorum.

Reduced to its lowest terms, rehabilitation of weakened foot consists in (1) measuring the degree of overstretching of the supinators of the weight bearing foot; (2) mechanically returning the bony contour by inwardly rotating the calcaneus, thereby restoring the relations of the lateral arch to Meyer's line and placing the pronators and supinators in equilibrium; and (3) by massage, active exercises and such other physical measures, as the condition of the tissues in individual cases suggests, stimulating the tibiales muscles to assume their full and proper function in the two distinct mechanical actions of locomotion.

Anatomical Diagnosis of Rabies. — Grouchmann, apropos of rabies, states that the clinical diagnosis is insufficient while inoculation with a portion of bulb of the dead animal requires too much delay. He would therefore make use of histological technique which can bring out the Negri corpuscles, the rabic nodules, neurofibrillary hypertrophy and rabic tubercles. The coexistence of these four finds is decisive while one or two alone may suffice. The Negri corpuscle is the most dependable single find. The evidence warrants a resort to the Pasteur treatment of the bitten.—*Journal de médecine et de chirurgie pratiques.*

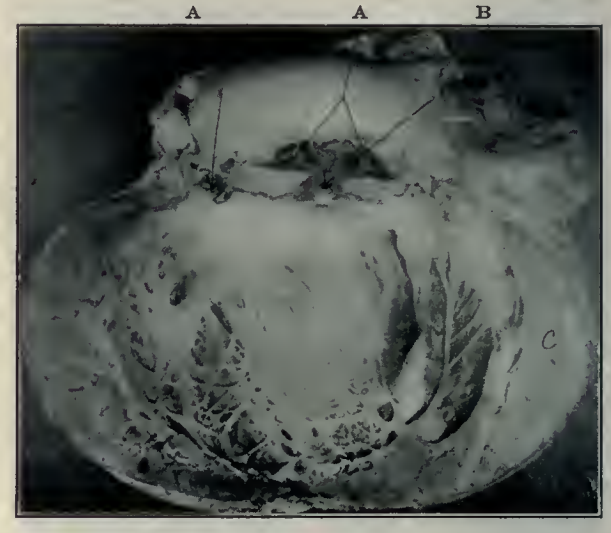
MALIGNANT ENDOCARDITIS.

By EDWIN SCHISLER, M.D.,
ST. LOUIS, MO.
PHYSICIAN TO THE ST. LOUIS CITY HOSPITAL.
AND
H. G. MOERSHEL, M.D.,
HOMESTEAD, IOWA.

MALIGNANT or ulcerative endocarditis, so called because of the tendency to local tissue destruction and the high mortality which it causes, may be acute or chronic.

It is always a secondary disease. It may be a local complication of a systemic disease like pneumonia, typhoid fever, epidemic cerebrospinal meningitis, influenza, and rarely rheumatic fever, or it may arise from a focal infection anywhere in the body due to gonococcus, streptococcus, staphylococcus, and less frequently to other infectious bacteria. There is always an associated bacteriemia.

The bacteria which are most frequently found in the infected heart tissue, vegetations, and contained thrombi, in the blood stream by cultures, are streptococci, pneumococci, and staphylococci.



AA, Acute massive vegetations. *B*, ulcerations and perforation of aortic valve. *C*, hypertrophic ventricle wall.

Streptococci are the most frequent cause and reach the blood stream and heart from septic wounds, the septic puerperal uterus, and other streptococcus foci about the head and elsewhere. While the *Streptococcus pyogenes* is the strain which causes most of the acute types arising from acute infections, the *Streptococcus viridans* may also cause the acute type, but usually is the cause of chronic malignant endocarditis.

Bacteriemia associated with general diseases named or due to a focal infection may not involve the heart. The normal endocardium is apparently resistant while old sclerotic processes of the valves and congenital deformities of the heart and proximal vessels predispose to malignant endocarditis. Hence malignant endocarditis most often occurs in individuals suffering from chronic valvular disease.

The morbid anatomy is essentially the same in all bacterial types in the acute form. Usually vegetations are present, often massive, especially when

due to pneumococcus or to *Streptococcus viridans*. Occasionally the vegetations are not large while necrotic destructive lesions are dominant in virulent infections and especially when staphylococci are the cause. (See the illustration.)

From the circulating blood thrombus formation occur the vegetations, necrosis of endocardium, superficial and deep, with perforation of valves and other destructive lesions. The infectious bacteria are present in great number in the vegetations, thrombi, and involved tissue.

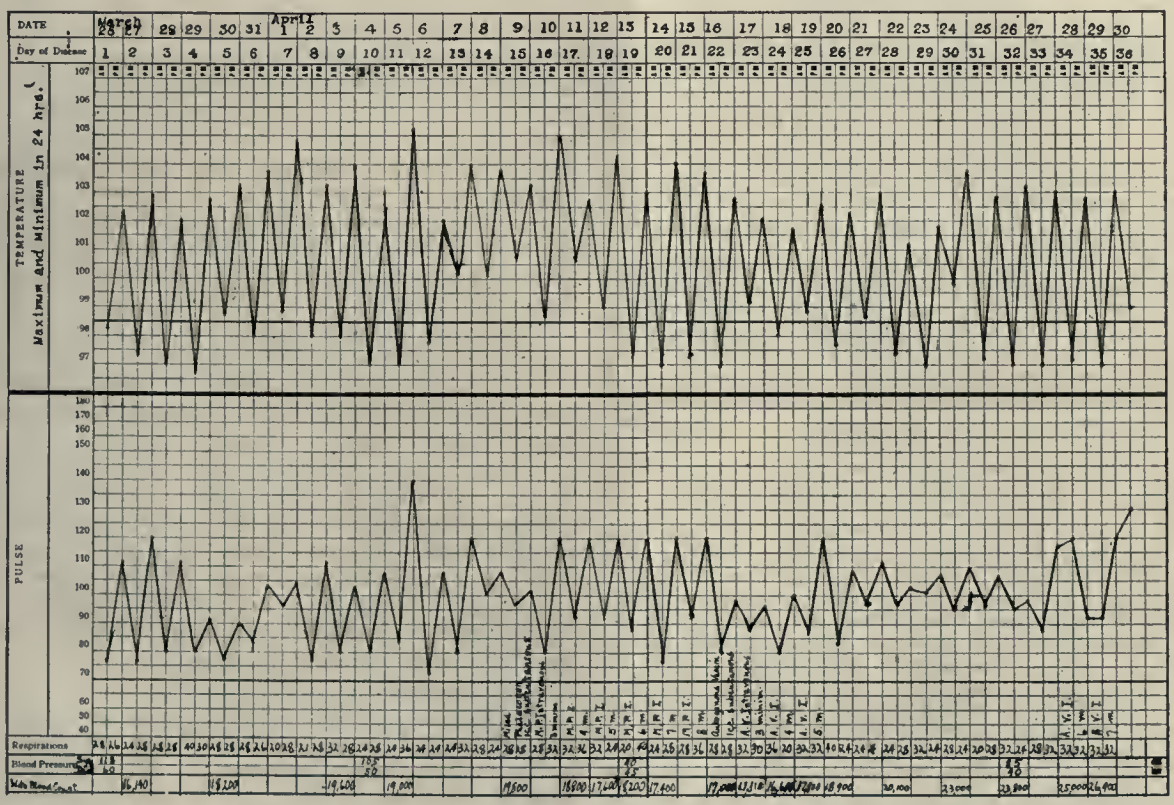
When malignant endocarditis occurs as a local complication of a general disease like pneumonia, rheumatic fever, cerebrospinal fever, or some other acute disease, it may not be recognized because the severe symptoms of the systemic disease may overshadow the local condition. As a rule the other symptoms of the general disease are intensified with evidence of failing heart, leading to a rapid fatal issue, and the endocarditis is recognized only at autopsy.

As regards characteristic symptoms which may lead to the diagnosis, the local heart condition is manifested by endocardial murmurs, supported by blood culture and increased leucocytosis. The septic type is marked by chills and an intermittent or remittent type of fever with severe sweats.

The diagnosis of malignant endocarditis is difficult, but is aided by blood culture.

You will note in the case report that the patient gives a history of general malaise of one month's duration and fever which developed gradually with steady pains in almost every joint. He had severe headaches and a chronic nasal catarrh indefinitely. On March twenty-third, three days before entrance, he was compelled to quit work on account of general weakness and extreme shortness of breath. The focus of infection here was questionable. After the cardiac findings and routine examination, a diagnosis of malignant endocarditis was made. The blood cultures made on April 3 and 8 showed a staphylococcus infection. The mixed phylacogen, 1 c.c. subcutaneously, had little effect. The following day 3 minims were given intravenously with a decided reaction. For 6 days the intravenous dose was increased by 1 minim daily up to 9 minims, without any noticeable improvement. On April 16, an autogenous vaccine was given. The results are shown in the temperature chart and stated in detail in the case report.

Mr. M. entered hospital March 26, 1918, conscious and rational, temperature 102°, pulse 112, respiration 25. He complained of general malaise of one month's duration, and fever which developed gradually with steady pains in almost every joint. He had had severe headaches and a chronic nasal catarrh for many weeks.



During the past week he developed loss of appetite and nausea, but no vomiting. On March 23 the patient quit work because of weakness and shortness of breath. No history of night sweats, cough, or sputum, no hemoptysis or precordial pain, no edema of extremities; loss of weight negligible, no palpitation.

Family history, negative.

Past History.—Ordinary childhood diseases, acute rheumatic fever at 5 years, following which patient developed almost complete deafness both ears. Had left testicle removed following an injury.

Social History.—White male, age 49, laborer and inventor, was married for two years, separated three years ago; admits gonorrhea 24 years ago, denies lues, smokes moderately, uses alcoholics very little.

Physical examination shows a well developed and fairly well nourished adult white male, skin flushed, speech high pitched, mentality normal, right epitrochlear gland palpable.

Scalp hair scant.

Eyes negative, pupils round and equal reaction to light and accommodation.

Nose negative.
Ears, almost complete deafness in both ears.
Mouth, teeth in poor condition, mucopurulent discharge in nasopharynx.
Neck negative.
Lungs negative.
Heart, no palpable friction, rub or thrill, apex impulse in sixth left interspace, left border 12 cm. to left of midline. At the apex, a faint blowing systolic murmur transmitted to axilla. In aortic area a loud systolic murmur transmitted to neck, A-2 accentuated.
Pulse 112, regular in rhythm, occasional drop beat; tension, systolic 118, diastolic 60.
Abdomen negative.
Genitalia, left testicle missing.
Reflexes, knee jerk diminished, no pathological reflexes.
Laboratory Findings.—Urine.—Sp. Gr. 1022, acid, albumin —, sugar —, granular casts, occasional red blood cell.
Blood.—Red count, 4,800,000 c.mm.; white count, 16,140 c.mm.; differential, 88 per cent. polymorphonuclear leucocytes; 11 per cent. lymphocytes; hemoglobin, 70 per cent.; blood negative for malarial parasites; Widal negative; Wassermann negative.
Fluoroscopic examination of chest negative.
Blood culture.—April 3, staphylococci; April 8, staphylococci.
For several days after admission the patient had severe chills three to six daily, followed by profuse sweats, marked anorexia, temperature 97° to 102° and 105°, septic curve, pulse 76 to 120. White count increased steadily to 19,800, the systolic murmur over apex increased daily in intensity and presently a loud blowing and roughened murmur was audible over the entire precordia.
On April 9 a mixed phylacogen, 1 c.c. subcutaneously, had little effect. The following day 3 minims of the phylacogen were given intravenously, resulting in a chill followed by profuse sweat. For six days the intravenous dose was increased by 1 minim daily up to 9 minims, without any noticeable improvement, and with but little change in the leucocyte count; however, the blood pressure which was S. 105, D. 50, on April 5, fell to S. 90, D. 45 on April 13.
On April 16, autogenous vaccine, 1 c.c. subcutaneously, was given, resulting in a profuse sweat but no chills. The following day 3 minims of the autogenous vaccine were given intravenously and continued for three days, increasing 1 minim daily. During this time the patient's appetite was ravenous. Little change in the leucocyte count which remained about 17,000; the maximum temperature was from 1° to 3° less than during the previous days, ranging from 101.5° to 103°. The patient suffered from profuse sweats and chilly sensations but no chills. The attacks of sweating usually appeared about three or four hours following the administration of the vaccine.
On April 20, the vaccine was discontinued because of the patient's objection to its use, and the profuse sweats diminished, and there was little change in the temperature curve; the pulse, however, remained high, irrespective of the temperature. On April 26, the patient developed a marked diarrhea and great weakness. The leucocyte count increased rapidly to 23,000 on April 28, when the autogenous vaccine was again given, 6 minims intravenously. The following day the patient complained of marked weakness and dyspnea, temperature curve remained the same, pulse remained at 110. The leucocyte count went up to 26,400. Blood pressure fell to S. 85, D. 40 on April 25.
On April 30, the patient's weakness became more manifest, the heart slightly more rapid and quite irregular, mentality comatose, and the patient expired.
During his last four days the patient appeared slightly jaundiced and in great mental distress; the systolic murmur became very loud and rough, audible over the entire precordia. Patient never complained of any pain in this area.
Autopsy No. 2393, May 1, 1918. By Dr. G. W. Schery.
Clinical Diagnosis.—Malignant endocarditis.
Limited autopsy.
Anatomical Diagnosis:
1. Malignant endocarditis.
2. Infarct of spleen.
3. Cystic kidney.
4. Acute parenchymatous and chronic interstitial nephritis.
5. Polyserositis of abdomen and thorax.
6. Congestion and edema of lungs.

2600 South Grand Avenue.

ADVANTAGES OF HOME OVER INSTITUTIONAL CARE.*

By MINER C. HILL, M.D.,
NEW YORK.

Boarding-out babies in private homes has been practiced since time out of memory. The foster mother was a good-hearted neighbor, or one who made it a business for profit. In either case proper supervision was lacking, and the results so far as the baby was concerned were poor, and the custom fell into disrepute.

That this type of care, under proper supervision, has many advantages over institutional care is not generally appreciated.

The development of modern hospital and nursery buildings, hygienically planned and and equipped, managed by specially trained attendants, would seem at first glance ideal and preferable to boarding out in tenement homes. The investigations of Dr. Henry Dwight Chapin of New York, and Drs. Holsclaw and Rude of San Francisco show that institutional care is far from ideal.

The latter investigators found a 50 per cent. mortality in the foundling asylums of San Francisco. Among the same type of infants boarded out in private homes under supervision the mortality was reduced to 12 per cent.

Comparing the mortality rates of sick children in the hospitals and sick children treated in the homes is not fair to the hospitals because they receive more serious cases. Hospital care for surgical conditions and many medical conditions is, and always will be, essential. But the writer is of the opinion that a great many medical cases now treated in the hospital ward can be more successfully cared for in the home.

Children away from their homes and parents are unhappy, homesick and often uncomfortable or even comparatively neglected. When they are discharged they go back to the old environment which may be responsible for the illness and which has not been influenced by their stay in the hospital.

If a child must have hospital care, the shorter the stay the better for the child.

We are all acquainted with the institutionalized baby; a hospital infant cured of his acute illness, showing an initial gain in weight, then stationary, then losing and too often a victim of some intercurrent infection. It has been the unhappy experience of some of us to see a "boarder baby" well and robust on admission, steadily decline under what was considered ideal institutional care. There is rarely a sufficient number of nurses to give the constant individual attention an infant requires. This is well illustrated by the fact that when a feeding ward is light the

* Read before Pediatric Section, N. Y. Academy of Medicine, March 11, 1920.

gains in weight are greater than when the ward is filled to capacity.

In addition to caring for the babies, there is so much routine ward work, such as charting, bed making, etc., the nurse has little opportunity to frolic with a baby during "playtime," that fifteen to thirty minutes before feeding is due.

In the home, time is always found to give affection as well as routine physical care, and it is not uncommon to see a foster mother holding a baby on her lap or carrying it about. This change from the prone position and the exercise unconsciously obtained undoubtedly improves the baby's general tone. Admitting the necessity and value of hospital care, we should bear in mind that its prolongation is bad for the baby, does not educate the parent and is expensive. Those of us who have had opportunity to observe results of institutional and home care, under the same supervision, are favorably inclined toward home care.

HOME CARE OF WELL INFANTS.

The Gramercy Nursery was opened March 1, 1916, as a temporary shelter for infants whose home care had become impossible through the illness or death of the mother (I might say in passing that this is an urgent problem deserving of more attention than is now given). This nursery had a capacity for seven babies, was well equipped and efficiently managed. During the year 1917 we handled 56 babies; the cost per child per day was nearly $3, and the average weekly gain was 4 ozs., and the mortality 4 per cent. The work was worth while, the results were good but the cost was excessive, owing to a constant overhead expense.

After consultation with Dr. Chapin, the nursery was reorganized on a boarding-out plan similar to the work of the Speedwell Society.

From October 1, 1917, to October 1, 1918—115 babies were cared for on the boarding-out plan at a cost of $1.29 per day with an average weekly gain of 5.15 ozs.; that is, in using the boarding-out plan, twice as many children were cared for with a greater weekly gain at less than half the per capita cost of institutional care. The latter plan was accomplished through the cooperation of the Babies' Welfare Association and the State Charities Aid Association in finding suitable boarding-out homes.

The greatest difficulty of the boarding-out plan is in finding suitable foster homes within a workable area, but the advantages of boarding-out care are so manifest that difficulties should not deter our efforts to extend the work.

HOME CARE OF SICK INFANTS.

The Health Center of the Bowling Green Neighborhood Association favorably illustrates what can be done in the home care of sick children. The Health Center is within easy access of all families registered.

Instruction in preparing formulæ, giving baths, enemata, ear irrigations, etc., is given the parent by the nurse at the Health Center and in the home.

During acute illness the case is referred to the Henry Street Settlement nurse who makes one or more visits daily as requested, and the Health Center physician, or family doctor, visits the home to direct the medical care.

With this equipment it is only necessary to send a few children to the hospital. Under such a plan the patients do well, are more contented in their own homes and the parent receives valuable instruction at a most impressionable time in the care of sickness and the prevention of recurrences. A reduction of the mortality rate for this district from 232 in 1913 to 59 in 1917 is a good index of the practicability of the Health Center idea.

The marked success of the home care of well children as proven by the results of the Speedwell Society, the Gramercy Nursery and of the children in the Bowling Green Neighborhood Association suggests a wider application of this plan.

If suitable boarding homes could be found in the neighborhood of the hospital, feeding cases after a few days observation in the ward could be transferred to the home and their subsequent treatment accomplished through daily visits by the internes or one of the attending physicians. In neighborhoods where there is no hospital it would seem practicable to have a small reception ward in connection with the Health Center. Here each acute case could be observed for a day or two, during which time the usual laboratory work, such as the von Pirquet test, Shick test, throat culture and vaginal smears made, and then the baby could be returned to its own home or assigned to a boarding home where the foster mother shows aptitude for the particular condition.

YEASTS FROM THE HUMAN COLON.

PROTOCOL OF LABORATORY STUDIES AS TO PATHOGENICITY.

By J. M. LYNCH and J. W. DRAPER, M.D.,

NEW YORK.

SURGEONS TO ST. BARTHOLOMEW'S HOSPITAL FOR DISEASES OF THE ALIMENTARY CANAL.

On June 13, 1919, a patient, O. I., complaining of severe headache and sciatica, was referred to Dr. Lynch. For four years he had been under treatment by specialists in this country and in Europe without showing any apparent improvement. He gave a history of auricular fibrillation, of tuberculosis in the left lung ten years before, and typhoid fever twenty-five years before. His physical examination was negative.

Previous to coming to this office a culture from his stool had never been made. Feces obtained from the rectum with a sterile platinum loop, when inoculated in glucose agar, yielded a profuse growth of yeast cells, associated with a diplococcus and extremely few colon bacilli. The profuse nature of the growth, and the fact that these organisms did not ferment sugar, aroused interest, and led to further investigations. The patient had never received the Fleischmann treatment. To exclude the possibility that the yeast was a chance occurrence, a new culture was taken from the patient on June 24. The same organism was isolated, and also what appeared morphologically to be a different type of the same yeast.

The culture obtained June 13 appeared to consist

of two types of yeast. Type 1, morphologically, is a small, spherical or oval organism of fairly uniform size, and rich in granular chromatin. It never forms any mycelium in ordinary culture media. Culturally, it produces only a granular sediment, and no clouding of the broth or film formation. Type II tends to be club-shaped, and forms a definite mycelium. It produces a film on the surface of broth cultures in addition to a granular sediment. The culture obtained June 24 contained Type I, but no Type II. A new Type III was present, which morphologically is elliptical, flattened, and vacuolated, and varies considerably in size. Like Type II, it also produces a definite mycelium and a film on the surface of broth cultures.

A saline suspension of a pure agar culture of the Type I yeast was injected into six rats, three intraperitoneally and three subcutaneously. After three and ten days, animals of each group were killed and careful autopsies made. Those injected intraperitoneally showed, scattered all over the peritoneum, many small and large rounded nodules, translucent, with centrally located whitish spots. The main mass of the injected material came to rest in the tissues of the greater and lesser omentum, about the liver, and beneath the diaphragm. In these localities the reaction was slightly different, and appeared as flattened masses of translucent tissue, showing deep-seated, scattered areas of opacity. Nodules were found on the surface of the kidneys and the liver, and even in the substance of the former organ. Type I yeast organism was recovered in cultures from these lesions.

Microscopical examination of the peritoneal lesions showed a granulomatous structure very suggestive of a tuberculous lesion. It consisted of a central area of suppuration and necrosis, surrounded by fibrous tissue containing many scattered epithelioid cells, in which were also localized smaller aggregations of epithelioid cells inclosing one to several multinucleated giant cells. A special stain was made of some frozen sections of the lesion in the kidneys, and large numbers of the yeast organisms were definitely seen in the tissue showing characteristic budding.

The three rats injected subcutaneously had developed a localized, tumorlike granuloma having a general similarity to the peritoneal lesions, but no metastases were found. Intravenous injection of mice resulted in death from embolism within twenty-four hours. Four rats were fed three feedings with a mixture of the yeasts, and twelve days after the first feeding two rats were killed and the gastrointestinal tract carefully examined, but the results were negative. A culture of the contents of the cecum was made, and only Type I of the yeast was recovered. The significance of the disappearance of the other types is unknown.

As yet the organisms have not been identified. Are we dealing with three different types of yeast, or are the different morphological and cultural characteristics attributable to the phenomenon of pleomorphism, a condition commonly observed in certain yeasts? This study is not yet sufficiently advanced to justify any conclusions as to the relation of these yeasts to the pathological condition. The known relations of the inner surface of the body, the intestinal epithelium, to the outer or skin, are, however, very intimate. Skin lesions due to yeasts are very common. From embryological and clinical viewpoints it would appear probable that what attacks one surface may attack the other. Further laboratory studies of this important question are being made.

MANIC-DEPRESSIVE INSANITY AND RAYNAUD'S DISEASE.

By E. H. P. WARD, M.D.,
WHITE PLAINS, N. Y.

Is it not possible that manic-depressive insanity is a form of Raynaud's disease affecting the frontal region of the brain? Osler defines Raynaud's disease as "a vascular change, without organic disease of the vessels, chiefly seen in the extremities, but occurring also in the internal parts, in which a persistent ischemia or a passive hyperemia leads to disturbance of function or to loss of vitality with necrosis." The incidence of Raynaud's disease is not in the majority of cases unlike that of manic-depressive insanity as regards *age*, and it occurs sometimes in several members of a family and especially in neurotic and hysterical patients. As stated above, it usually affects the extremities, and the ischemia due to constriction of the blood-vessels to a part is followed as a rule by a condition of asphyxia, during which the part becomes blue, and then there succeeds a stage of hyperemia. The condition may persist from a few days to several months and the attacks may recur at intervals of a year or more and result in edema of the extremities and gangrene. According to Osler, "the disease is the result of some as yet unknown instability of the vasomotor centers," and as complications, temporary amblyopia, due to spasm of the retinal vessels, transient aphasia, and transient hemiplegia have been met with. In one case there were three attacks of aphasia with hemiplegia from which complete recovery took place, these symptoms being associated with the features of Raynaud's disease, and the patient dying in a severe attack with pain in the right hand, gangrene to the elbow, and coma. Furthermore, epilepsy has been associated with a great number of cases of Raynaud's disease and in one case mentioned by Osler the attacks of epilepsy occurred only while the patient was suffering from Raynaud's disease.

Now I believe that these cerebral complications are undoubtedly due to a vasomotor change in the blood-vessels of the brain, just as the disease in the extremities is due to vasomotor changes. An ischemia of the motor areas of the cortex would probably lead to temporary loss of function and produce the symptoms of a hemiplegia, while a hyperemia might lead to the exaggerated activity of an epileptic attack. There has been some doubt as to whether there is any vasomotor control of the cerebral arteries, but I believe the evidence tends to show that there is such control although it is not so complete as in the arteries elsewhere. And this probably explains why the vasomotor constriction does not in the brain produce necrosis of the affected parts as it does in the extremities. Now, in the case of manic-depressive insanity, the region of the brain affected is that of the frontal lobes. Their function in health is to exert a restraining

influence on the lower centers of the brain that comprise the motor areas, the centers of intellectual activity and of the emotions, and probably of the areas concerned in the reception of stimuli from the various sensory organs. If this restraining influence of the frontal lobes is exaggerated, the function of the lower centers and areas is depressed; whereas, if the restraint is diminished, all these lower centers take on an increased and exaggerated activity—but an activity that lacks direction and control and serves no useful purpose.

Now, if the blood supply to the frontal region is greatly diminished, its functions will be interfered with and it will no longer exert its normal restraining influence on the lower centers, and we get a condition of overactivity of these lower centers without any direction and the symptoms may vary all the way from slight exaltation to mania. If, on the other hand, there is hyperemia of the frontal region, its function is stimulated to overactivity, and it exerts such an exaggerated restraint upon the lower centers that depression occurs. Furthermore, since the higher psychic functions of the personality and moral character are probably dependent on the frontal centers of the brain, any change here would lead to alterations of the personality. Thus this hypothesis will competely account for the manifestations of manic-depressive insanity, and also for the fact that no dementia or necrosis results from even prolonged and repeated attacks. For the vasomotor control of the cerebral vessels is not powerful and complete enough to shut off the blood supply completely; it is only more or less diminished.

Furthermore, on this basis we can account for many of the characteristic symptoms that accompany manic-depressive insanity—the flushing of the face, the coldness and lividity, and even gangrene of the extremities, and also the characteristic edema of the extremities. Opposed to this is the hypothesis that manic-depressive insanity is due to toxins resulting from a condition of intestinal infection, and the fact that many patients have in their blood agglutinins to certain strains of streptococci, together with a well-defined leucocytosis. This, I believe, is a secondary condition resulting from intestinal stasis and the lowering of bodily tone generally, although no doubt there is in all cases more or less toxemia, if only from intestinal putrefaction and the accumulation of waste products. We should hardly expect such complete recovery after prolonged and repeated attacks if the disease were due entirely to a toxemia severe and prolonged enough to account for the symptoms. And why should toxemia give us in one case, or at one time, exaltation, and in another depression? Also we might expect to find fever, as a characteristic feature, which we do not.

As to the cause of this vasomotor instability affecting the frontal region, it might possibly be itself the result of a toxemia affecting the vasomotor centers, and in this way the disease might be due primarily to toxins acting not on the frontal areas so much as on the vasomotor center. But I think this is very doubtful. It is more likely a disturbance of the normal vasomotor balance. Action and reaction are equal and opposite, and there is no reason why this law should not apply to the vital functions as well as in mechanics. In the child, where vasomotor control of the cerebral vessels is probably more complete, joy and sorrow, rest and play (*i.e.* work) succeed each other at short intervals; in the adult, the interval is prolonged, but not unduly so without danger. Too long or too intense application of the attention (which probably becomes operative through vasomotor control), without relaxation or change, disturbs the natural balance and suddenly the pendulum breaks loose and swings the other way. Perhaps too great repression of the sexual functions may form the basis of the disturbance in some cases. Possibly those who have been wont to seek their relaxation in alcoholic indulgence may in some cases suffer from manic-depressive insanity now that their accustomed mode of relaxation is denied them.

As to the *treatment* of this disorder, the following measures would seem to be indicated according to this hypothesis: rest in bed without food for twenty-four hours and then a greatly restricted diet, consisting of gruel, milk, eggs, etc.; no carbohydrates, as they make the intestinal contents a good culture medium for bacteria and especially for the streptococci (note the liability to streptococcic infection in diabetes, where blood and tissues are overloaded with sugar); Epsom salts in large doses, repeated as required, to clean out the intestinal tract, eliminate toxins from the blood, draw the blood from the brain, and diminish the volume of blood generally, thus reducing the strain on the heart and the vasomotor centers; hydrotherapy, especially prolonged hot baths and the needle spray with very hot water applied to the spine, especially in the cervical and lumbar regions. As to drugs, strychnine would be indicated, especially in the stage of depression; whereas the bromides might be of use in the stage of excitement, but not in sufficient quantity to depress the bodily tone too much.

Tea and coffee should be forbidden in the depressed state, since the higher psychic functions of the frontal areas are already overstimulated by the hyperemia; whereas, in the maniacal stage, where these centers are depressed by lack of blood, tea and coffee in moderation might be helpful. Nitroglycerin might be of value in both stages. In the depressed stage alcohol might prove of value, and cheerful music and other means of diversion, such as dancing, when strength permits. Above all, it is important to use drugs with care and tentatively, with the idea of holding the pendulum from swinging too far in the direction either of depression or excitement, hyperemia or ischemia of the frontal areas, rather than to attempt to push it back to normal. If vasomotor instability is the essential feature of the disease, and the tendency is to swing from one extreme to the other, we must take care not to exaggerate this tendency by the use of drugs.

Cushing has shown that, in Raynaud's disease of the extremities, momentary application of the tourniquet may restore the circulation to its normal condition. Possibly momentary compression of one of the carotids might similarly be of value in manic-depressive insanity, but should not, of course, be attempted except by an expert.

DIAGNOSIS OF THE MYOCARDITIC SYNDROME IN TYPHOID FEVER.

THE diagnosis of the myocarditic syndrome of suprarenal insufficiency in children with typhoid fever is an affair of some difficulty on account of the possible confusion of the symptoms composing it with those encountered ordinarily in typhoid, as well as those resulting from a morbid change in organs other than the suprarenal glands. The involvement of the latter may be rather marked and it is clear that all degrees in the clinical manifestations will be the consequence. This is not the place to discuss the problem of the causal infection, but in all the cases reported by Chasseray—of which there were nine—a serodiagnosis or hemocultur was made and in each case gave a definitely positive result. It is the diagnosis of this complication that it is essential to make.

In some instances the diagnosis of the cardiovascular complications is self-evident, but until recently, on account of the similarity of the symptoms, these would have been regarded as those of myocarditis. For example, a child develops a typhoid fever which progresses regularly, and it is known that the patient had a cardiac lesion previously, so that it is not to be wondered at that the cardiovascular symptoms assume an unusual intensity. But the intensity of these phenomena which are in the foreground from the onset of the typhoid in no way correspond to the severity of the nervous or digestive symptoms. There is little asthenia or gastrointestinal disturbance. The influence of opotherapy is practically *nil*, while that of digitalis is somewhat though not very much better. In a case such as this it is entirely logical to conclude that the cardiac process is due to typhoid infection because, excepting the cardiovascular symptoms, there are none of those characteristic of suprarenal insufficiency.

Take another case as an example. At the end of the second week of typhoid fever cardiovascular disturbances appear very suddenly, with tachycardia and arrhythmia. The heart dilates, the blood-pressure falls, but far from being foremost these phenomena remain in the background of the clinical picture, while the nervous and digestive disturbances—asthenia, vomiting, diarrhea—are prominent. Emaciation is rapid, but with opotherapy, which failed in the preceding case, the most serious phenomena rapidly retrogress. The stupor disappears, the temperature drops, urine increases, the digestive disturbances decrease, but are slower in their retrogression. On the other hand, the blood-pressure quickly rises, the heart-beats diminish, the pulse becomes normal, and by the end of the typhoid attack all the cardiovascular symptoms will have disappeared. In such cases the diagnosis which had been made of myocarditis was manifestly a mistake and the causes of the syndrome must be looked for elsewhere.

The proof obtained by opotherapy in favor of suprarenal lesions is considerable, but one must not generalize too much, and because adrenalin works well it is not conclusive proof that the suprarenals are involved. Adrenalin is a marvelous hypertensive, which, when judiciously exhibited, will render great service in typhoid fever and the majority of depressive states. The favorable effects of such medication are not proof positive of a morbid change in the suprarenals and it is well to mistrust this therapeutic criterion although its services are to be resorted to. Before reaching a conclusion, all the clinical proofs must be examined and the action of adrenalin should be taken only in confirmation of a diagnosis already made. Unfortunately, the symptomatology is not always so distinct, and the diagnosis is made more difficult by the prominence of certain symptoms, since suprarenal insufficiency may assume one of three types, namely, the myocarditic, a pseudomeningeal, and a pseudaperitoneal. Other than in the myocarditic syndrome, a confusion must not be made between the cardiovascular type of suprarenal insufficiency and the phenomena of nephritis occurring in typhoid. The study of the blood-pressure acquires in these cases a great importance if it reveals hypertension, and besides edema will soon appear and the liver rapidly increase in size.

The diagnosis of the pseudomeningeal type from that of the true meningeal state in the typhoid of childhood must be gone over, and in these circumstances clinical confusion is possible, so that lumbar puncture should be resorted to; but it must be remembered that in some authentic instances of meningitis the result has been negative. Finally, in cases where the severe vomiting, abdominal pain, and changes in the pulse might lead one to fear a peritoneal complication resulting from intestinal perforation or hemorrhage, an attentive study of the temperatures, examination of the stools and abdomen, and the seat of the pain will offer certain diagnostic data; but for all that the diagnosis is difficult, especially at the onset, on account of the prostration and agreement in the date of appearance of the most usual of the two syndromes. It is a careful study of the evolution of the symptoms and of the manner of their retrogression under opotherapeutic measures that will remove all doubt.

ISOAGGLUTININS IN THE BLOOD OF INFANTS AND CHILDREN.

It is now well over ten years since Jansky first showed that in respect to their isoagglutinin content in the blood all individuals fall into four groups. The investigation and elaboration of this phenomenon has been of the greatest service in the development of blood transfusion as we now know it. It is certain that the greatest dangers attendant upon this operation are those connected with incompatability of the bloods of the donor and the recipient. These facts are so firmly established and the methods of determining blood groups so rapid and reliable that no surgeon is now willing to countenance transfusion without a previous grouping of the donor and the recipient. This is so in the case of adults. Where infants are concerned, opinion has not been quite so certain. Some investigations seemed to show that the new-born were not separated into blood groups and many were of the opinion that young infants could be transfused from their mothers without the necessity of a preliminary grouping.

A careful investigation of this subject has recently been undertaken by Happ, who finds (*Jour. Exper. Med.*, 1920, xxxi, 313) that no matter what the age of the infant it is unwise to transfuse it with its mother's blood without performing the preliminary tests. He found that the group of the corpuscles was established before that of the serum, but that 16.3 per cent. of infants of one month or less out of 49 examined, presented a definite group determination. By the time that the age of one year was reached practically all children showed establishment of the blood group. It is further important to note that in seven cases in which both mother and infant were examined, and where the group of the infant was fixed, in only one instance were both of the same group. Any consideration of these figures will lead to the conclusion that it is *never* safe to proceed with a transfusion without having first made the necessary tests to determine the compatibility of the bloods.

It is remarked that the author employs the nomenclature as introduced by Moss; that is, serum containing no agglutinins is designated as group I and corpuscles that are inagglutinable belong to group IV. It is true that the work of Moss was done independently of that of Jansky, but the latter has a distinct priority and certainly deserves consideration on historical grounds. The existence of the two systems of nomenclature as used by these two authors has introduced an element of confusion into the situation especially apparent in the use of the professional donor. It could be wished that some of the important national societies interested in this subject would decide as to which system should be adopted. At the present time annoying errors are repeatedly being made because professional donors are not aware that it is necessary to state according to what system their grouping has been done.

THE TETANIC TYPE OF UREMIA.

The reality of tetanic uremia has been founded until now upon cases whose demonstrative value has seemed to be insufficient, but one or two cases have been studied at Paris recently which appear to prove that uremia may really simulate tetanus. The instances of tetanic uremia published to date may be conveniently grouped under four heads as follows: (1) The mixed form of nervous uremia, at the same time epileptic and tetanic; (*a*) cases of convulsive uremia of the epileptic type accompanied by some more or less persistent contractures, and (*b*) cases of convulsive uremia of the epileptic type accompanied by a tetanic syndrome simulating tetanus. (2) The purely tetanic form comprising: (*a*) pure cases of localized contractures in subjects having albuminuria or Bright's disease, and (*b*) pure cases of the tetaniform syndrome distinctly characterized, simulating tetanus. It is the latter group of cases which are especially prone to give rise to mistakes in diagnosis.

The general pathogenesis of tetanic uremia probably does not differ in any respect from that of nervous uremia in general—epileptic, meningitic, or delirious. It is evidently due to the retention in the blood and serum, and perhaps the formation in the organism following retention of the elements of the urine, of toxic substances selectively acting on the nervous system. Such is the classical theory which has been generally accepted.

But the *ensemble* of work done on the subject during the past few years, particularly the researches of Widal and his coworkers, give the impression that the initial and major factor of these accidents is retention of urea in the blood—azoturia. Other than this general notion, which seems to be on the point of being completely verified, nothing of a precise nature is known of the mechanism of the accidents and notably the causes which make uremia manifest itself sometimes by delirium, at other times by clonic or tonic convulsions or by somnolence and coma. The fact that these manifestations are very often associated would lead to the supposition that the same toxic principles which act in all the cases provoking distinctly variable reactions, either because of their different quantity and proportions in the organism which they impregnate, or because of a special susceptibility of the organism itself. There is reason to suspect that these toxic substances are capable of acting on the cerebrospinal cells in somewhat the same way as the tetanic toxin of Nicolaier's bacillus. All this is merely hypothesis and somewhat hazy at that, but as the reality of tetanic uremia is still under discussion, it is not astonishing that its pathogenesis has not been advanced more than it has.

The differential diagnosis of pure tetanic uremia, distinctly tetaniform, is especially with that of tetanus, cerebrospinal meningitis, strychnine poisoning, and perhaps hysteria. A positive diagnosis will be principally based upon the coincidence of

the clinical signs of uremia—albuminuria, myosis, polyuria, pollakiuria, symptoms of renal heart, Cheyne-Stokes respiration, and high blood pressure —with more or less generalized persistent contractures; also on the paraclinical researches, such as the dosage of the azotemia, the urea contained in the cerebrospinal fluid, and the cytology of this fluid.

The Pharmacology of Hydrochloric Acid.

The pharmacology of certain drugs is incompletely understood. As a matter of fact the pharmacology of no drug is completely understood, but certain drugs are sometimes prescribed, concerning the functions and action of which a great deal of ignorance prevails. For example, hydrochloric acid is very frequently prescribed, mainly to overcome a deficiency of acid. The best mode of its administration, however is often overlooked and in consequence the digestive action of the drug is futile. Dr. W. A. Bastedo who was the president of the American Gastroenterological Association at its twenty-second annual meeting held at Atlantic City, N. J., June 9 and 10, 1919, made the pharmacology of certain drugs the subject of his presidential address, published in the *American Journal of the Medical Sciences*, January, 1920. He pointed out a fact that is by no means always recognized, namely, that the administration of hydrochloric acid alone is practically useless for the purpose of digestion, and really to judge of its merits as a remedy, it must have all the factors for its action. In other words pepsin must be administered with it. Moreover, the products of the action of pepsin and hydrochloric acid on protein are themselves capable of exerting a strongly stimulating effect on secretion. Speaking of the action of hydrochloric acid in achylia gastrica, Bastedo says that from experiments based on the introduction of hydrochloric acid alone, without its natural congener pepsin, it is evident that with single doses of a strength that can be swallowed, the acid titer of the stomach contents may be distinctly raised even to the normal. The results that might be expected from this are: (1) Successful protein digestion in the stomach when sufficient pepsin is also introduced; (2) Slowing of the emptying time of the stomach by re-establishment of the pyloric closure reflex; (3) Restoration of the normal antiseptic action in the stomach; (4) The proper formation of secretins; (5) Normal liquefaction of the stomach contents by the added fluid. The possible drawbacks to its use are the establishment of pyloric closure in an already slowly emptying stomach, the production of gastric irritation, and the development of a mineral acidosis from its daily use over long periods of time. Conclusions as to the administration of hydrochloric acid may be set down thus: (1) In cases of achylia gastrica, whether or not accompanying pernicious anemia, a deficiency of acid may be partially overcome by hydrochloric acid medication. (2) For digestive purposes hydrochloric acid should always be accompanied by pepsin. (3) In the achylias with diarrhea, acid promises a more noticeable result than in the achylias without diarrhea. (4) When acid produces sourness and stomach irritation its use should not be continued. (5) To avoid acidosis alkalies should be given during the same period, though not at the same time as the acid, the amount required being judged by the effect on the urinary reaction.

Syphilis and Graves' Disease.

Careful students of exophthalmic goiter, which is a condition of interest alike to ophthalmologists, neurologists, internists, surgeons, gynecologists, and endocrinologists, will perhaps be surprised to hear that it is often of syphilitic origin. Certainly the two have usually been kept apart in practice and theory as well, although Levy-Franckel, writing in *La Médecine* for November, 1919, i, 2, assures us that since 1911 evidence of the association of the two diseases has been accumulating. Before that date Pierre Marie had noted the occurrence of syphilis in a number of subjects with Graves' disease. In 1911 the late distinguished Professor Gaucher, in association with the author, announced that sufferers from the latter malady might benefit by antisyphilitic treatment. Sainton and later Schulmann noted that familial and conjugal cases of Graves' disease were sometimes due to the underlying syphilis shared by the subjects. It was probably not an entire coincidence that in these syphilitic goitrous subjects severe specific lesions had existed in the vicinity of the thyroid—mouth, throat, and rhinopharynx. The nearness here is not sufficient to suppose any extension to the thyroid gland, so that the connection is obscure. The gland is usually involved in the second year of the disease, although in some cases tertiary syphilis has preceded the lesion. Save for the possibility of specific thyroiditis in a few cases, the pathology is obscure. Apparently specific thyroiditis has never been known to cause typical Graves' disease, though quite recently the affection has been described in heredosyphilitics. The most striking fact is this, that while in ordinary Graves' disease iodides are contraindicated because of the state of hyperthyroidism, in the luetic variety this drug does good. Another is the general statement that in certain cases of tabes, exophthalmos has been a forerunner.

Malignant Precocious Syphilis.

Syphilographers are aware of a type of this affection in which neither the spirochete examination nor the Wassermann is positive, which presents no secondary phase and is uninfluenced by treatment. It is this type which causes a belief that we are not confronted by syphilis but a new or rare congener. But this type shades into others in which one or more of these negative characteristic are absent; so that there appears no warrant for suspecting that it is anything but syphilis. Other attributes of malignant precocious syphilis are the destructive nature of the lesions, the tendency for relapses to succeed one another rapidly and the curious spontaneous cure which may follow years of hardship for the patient. Every new report of this affection should be scrutinized for the presence or absence of the characteristics of the extreme case. Queyrat and Mouquin have recently reported one

which is mentioned in *La Presse Médicale* for January 31, 1920, xxviii, 9. The affection began with fever and great malaise. Spirochetes were absent and the Wassermann was only partially positive. Unlike some of these cases the disease yielded promptly to arsenobenzol. The authors are inclined to accuse a special strain of spirochete in order to explain so many vagaries. Gougerot said in discussion that these cases of malignant syphilis could be transmitted by subjects with ordinary syphilis; and therefore he could not endorse the special strain hypothesis. Ravaut was surprised to find no evidence of meningeal reaction in the spinal fluid of these patients; for in theory there should be such a reaction, as early syphilis, as a rule, does present one, and in theory the more intense the infection the greater the likelihood of meningeal congestion.

News of the Week.

Scholarships for Physicians.—The Endowment Fund Committee of the New York Post-Graduate Medical School and Hospital has announced that the $100,000 recently contributed by Mrs. Henry R. Rea, in memory of her parents, Mr. and Mrs. Henry W. Oliver of Pittsburgh, will be used to establish twenty scholarships for the benefit of country physicians who are unable to pay for the courses of post-graduate instruction. In awarding the scholarship prizes the Committee will consider the possibilities of public service of each candidate, and the recommendations of the State and County Medical Societies will be considered. The scholarship awards will not be local, but will be distributed over the country.

Social Hygiene Workers Needed.—In connection with the Government compaign for the eradication of social diseases, the Civil Service Commission has announced examinations for the following positions under the Interdepartmental Social Hygiene Board: Director of bureau, division, or section of protective social measures, $3,500 to $4,500 a year; supervisor of protective social measures, $2,800 to $3,600 a year; field agent, protective social measures, $1,800 to $3,000 a year; special assistant agent, protective social measures, $900 to $1,500 a year. Receipt of applications for these positions will close on May 4. The Commission has also announced an examination to be held on May 5 to fill positions of assistant field agent in protective social measures, under the Interdepartmental Social Hygiene Board. The salaries of these positions range from $1,200 to $2,000 a year. In this examination the competitors will be assembled for written tests. Both men and women are eligible. Further information and application blanks may be obtained from the U. S. Civil Service Commission, Washington, D. C., or the local board of civil service examiners at the postoffice or customhouse in any city.

Collaborating Epidemiologists Appointed in Ohio.—One hundred and forty Ohio health commissioners have been appointed assistant collaborating epidemiologists by the United States Public Health Service. These are commissioners who have been appointed in both the municipal and general districts of the State under the Griswold Health Law. With their appointment they also receive the privilege of using franked mail for their morbidity reports, and these reports may be submitted to the State Department of Health in the franked envelopes. As other districts, which have not as yet appointed their commissioner make the choice, each will be given the same privilege as the ones now holding it. The men who have been chosen by the U. S. Public Health Service will receive $1 a year for their work. Franked report cards have been placed in the hands of 8089 Ohio physicians that their reports of communicable diseases may be submitted to the State Department of Health more quickly than formerly.

Children's Bureau in Belgium.—A national children's bureau has been established in Belgium, according to advices received from the Children's Bureau of the U. S. Department of Labor. It is interesting to note that the law establishing this bureau went into effect several months after the child welfare conferences held under the auspices of our own Children's Bureau in the early summer of 1919. Three child welfare experts represented Belgium at that time. The functions of the Belgian bureau are to "encourage and develop the protection of childhood, and especially to further education with regard to rules of child hygiene and to assist in their application, whether in families or in public or private child-caring institutions; to promote the organization of agencies interested in child hygiene, and to assist them by subsidies or otherwise; to assure supervision by the administrative authorities and physicians over the agencies thus protected." The bureau is directed by a board of forty members, called the "Conseil Superieur des Oeuvres de l'Enfance." This board has the decision on all questions relating to the protection of children; it issues orders concerning the functions of subsidized agencies; it takes necessary measures for the protection of children within the limits of the law; and determines the use of funds at the disposal of the bureau.

Bonuses Opposed by Nurses.—The National League for Nursing Education, the National Organization for Public Health Nursing, and the American Nurses' Association, at a joint session held during the recent convention in Atlanta, went on record as opposing the payment of a flat bonus to ex-service men and women, and as favoring the plan for land grants and long-term loans, and for increased payments to those disabled during war service.

Diet Kitchen Association Work.—The New York Diet Kitchen Association, in its annual report recently issued, chronicles the fact that only eighty of the 8,071 babies under its care died during 1919. During the year the association took care of 1,695 children between two and six years of age, 6,870 mothers, and 882 expectant mothers. During this period 733,394 quarts of milk were dispensed. A "war brides" clinic was established for the wives of soldiers returning from overseas. Conferences for children of pre-school age were included among the activities of the organization.

Cincinnati Academy of Medicine Honors Mem-

bers.—At a recent meeting of the Cincinnati Academy of Medicine, Dr. Byron Stanton, Dr. S. C. Ayres, Dr. J. C. McKinzie and Dr. A. P. Mathews were made honorary members. Dr. Stanton, the oldest member of the Academy, has been on the roster for sixty years. The following new members were admitted: Dr. Reed A. Shank, Dr. E. J. Kennedy, Dr. H. A. Haysel, Dr. A. R. Johnson, Dr. V. W. Fischbach, Dr. Ethel Winston and Dr. Salmer Siebler.

Massachusetts Vaccination Bill.—The Somerville Medical Society recently passed resolutions condemning Senator Joseph O. Knox of Somerville for the part he played in the defeat of the vaccination bill in the Massachusetts Senate. The Society went on record as favoring vaccination for all school children.

Health Officers Meet.—The tenth annual convention of the North Carolina Health Officers' Association was held in Charlotte, April 19, under the presidency of Dr. E. F. Long of Lexington.

Medical Society Elections.—The New London (Conn.) Medical Society, at its annual meeting April 1, elected the following officers for the ensuing year: *President*, Dr. Hugh B. Campbell, Norwich; *Vice-President*, Dr. C. I. Ferrin, New London; *Secretary-Treasurer*, Dr. A. C. Freeman, Norwich.

French Congress of Medicine.—The fourteenth *Congrès Français de Médecine* will be held at Brussels May 19 to 22 inclusive, under the presidency of Professor Henrijean. The Secretary General is Professor René Verhoogen.

Bequeaths Body for Scientific Study.—Dr. Joseph Simms, a well-known lecturer and traveler, who died of cerebral hemorrhage in New York City on April 11, 1920, in his eighty-seventh year, bequeathed his body to Dr. Edward A. Spitzka for scientific study. The brain of Dr. Simms, removed eighteen hours after death, weighed 1520 grams (53.58 ounces avoir.) and has been preserved by Dr. Spitzka for the detailed study of its morphologic features in comparison with the brains of other notable men.

Physician to Run for Congress.—Dr. W. N. Price of Richmond, Me., will be a candidate for Congress from the second district when the primaries for the Democratic nomination for representative are held in June.

Insane Asylums Crowded.—According to the annual report of the New York State Hospital Commission for the last fiscal year the thirteen civil State hospitals for the insane, which were built to accommodate 29,344 patients, house 35,579—6,235, or 21 percent. beyond their certified capacity. This overcrowding continues despite the expenditure, last year, of $1,033,380 for new construction, repairs and improvements.

Texas Optometrists to Test Medical Practice Act.—An optometrist of Dallas, Texas, who was recently arrested on a charge of violating the State Medical Practice Act, has announced his intention of making his a test case. It is also the intention of the State Optical Association to make a thorough test of the validity of the State Medical Practice Act in so far as it relates to the practices of non-medical optometrists.

Salvation Army Expenditures.—In a summary of the annual report of the Salvation Army it is stated that the organization erected forty-three provincial and divisional headquarters for fresh-air camps during the year 1919, put up other needed structures for expansion service, and paid off more than $1,000,000 of mortgages. The total operating expenses during the year were $13,257,522.

Physicians Needed in Serbia.—According to Captain O. Holstein, Field Artillery, U. S. A., who has just returned to this country from overseas, and who was in Belgrade a year after the armistice, says there is a shortage of medicine and hospital supplies in Belgrade. There are only 120 physicians to attend to 7,000,000 people in Serbia. In Serbia and Jugoslavia there are 500,000 orphans to be cared for.

Bequest to Phipps Institute.—The family of Henry Phipps recently gave $500,000 to the Henry Phipps Institute of the University of Pennsylvania.

Dr. Otto V. Huffman of Brooklyn has accepted a position on the faculty of the Post-Graduate Medical School and Hospital in the Department of Internal Medicine, and has moved his office to 771 Madison Avenue, New York City.

Dr. Benjamin Jablons has returned to New York City, after an absence of five years, during which time he served with the American Ambulance Hospital of Paris, returning to the United States after the first year of the war to accept the directorship of laboratories of the Saint Francis Hospital of San Francisco, California. On the entry of America into the war, Dr. Jablons returned to France with the American Expeditionary Forces and was attached to the Central Medical Department Laboratory. Previous to his release from military service, Dr. Jablons was connected with the Army Medical School of Washington, where he taught Anaerobic Bacteriology and completed researches begun in France on Wound Bacteriology.

Charitable Bequests.—Under the terms of the will of Mrs. Anna M. Sandham, widow of the late Dr. George A. Sandham, among other bequests the College of the City of New York will receive $30,000 for the maintenance of a chair of philosophy, $7,500 for a medical preparatory fellowship; the Woman's Hospital, New York City, will receive $5,000; the hospital of the Dutch Reformed Church of this city, $5,000; St. Luke's Hospital, for a bed for consumptives, $5,000.

Obituary Notes.— Dr. George W. Seibert died at Lebanon, Pa., on March 30 of complications resulting from injuries following a fall, at the age of 65 years. He was graduated from Jefferson Medical College in the class of 1879.

Dr. Harry Waldo Kimball of Providence, R. I., died of erysipelas, March 28, after a short illness. He was 52 years of age, and was graduated from the Medical School of Maine at Portland in 1891, specializing in dermatology. He was a member of the American Medical Association and of the state and local organizations. He was a member of the visiting staff, dermatological service, of the Rhode Island Hospital, and for two years before his death he had held the rank of Major in the United States Public Health Service.

Dr. W. A. Yeagy died of carcinoma at Dillsburg, delphia on April 6 at the age of 53 years. He was graduated from Jefferson Medical College in the class of 1890.

Dr. Wellington R. Hearing died at Philadelphia April 1 at the age of 42 years. He was graduated from the medical department of Temple University in the class of 1909.

Dr. Elmer E. Gibble died of pneumonia at Philadelphia on April 6 at the age of 53 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1893.

Dr. Elizabeth S. Kingman Horr of Waterford, Me., widow of the late Dr. O. A. Horr, died suddenly April 1 at the age of eighty-seven. She was graduated from the Women's Medical College of New York in 1872, and for many years practised with her husband in Lewiston, Me., returning to her old home in Waterford shortly after his death and her own retirement a number of years ago.

Dr. Leonard St. John of Chicago, one of the founders of Rush Medical College, and for ten years attending surgeon at the County Hospital, died of apoplexy April 2, at the age of 67. He was graduated from McGill University, Faculty of Medicine, Montreal, in 1872. He was a fellow Royal College of Surgeons (1873), a member of the American Medical Association and other national and local organizations, and during his long residence in Chicago had held various important hospital appointments.

Dr. George E. Fulton of Bluffton, Ind., died from influenza-pneumonia April 3 at the age of 64. He was graduated from Miami Medical College, Cincinnati, Ohio, in 1878. Dr. Fulton was in the Indiana House of Representatives in 1889 and 1891.

Dr. Joseph A. D. Jacques of Marlboro, Mass., died of cardiac disease April 5 in his forty-third year. He was graduated from the medical department, Laval University, Quebec, in 1901. He was a member of the Massachusetts Medical Society.

Dr. James T. Searcy of Tuscaloosa, Ala., died April 6 at the age of 80. He was graduated from New York University Medical College in 1867, specializing in neuropsychiatry. For many years he was superintendent of the Alabama Bryce Insane Hospital, and was a frequent contributor to medical literature. He was a member of the American Medical Association.

Dr. Edward Thayer Twitchell of Boston, Mass., died recently at Santa Barbara, Cal., where he had gone to recuperate from the effects of overwork during the influenza epidemic. He was graduated from the Medical School of Harvard University in 1886, specializing in obstetrics. He was a member of the American Medical Association and state and local organizations.

Obituary.

JAMES WRIGHT MARKOE, M.D.,

NEW YORK.

Dr. James Wright Markoe of New York City was shot by an assassin, evidently insane, during the services in St. George's Church, Stuyvesant Square, Sunday morning, April 18, dying shortly after reaching the Lying-In Hospital, to which he was immediately carried. Dr. Markoe, who was a vestryman of the church, was passing the contribution plate during the offertory, and as he approached the man, the lunatic drew a pistol from his pocket and fired, the bullet striking Mr. Markoe in the forehead. The man then ran out into Stuyvesant Park, where he was seized. Dr. George E. Brewer, who helped capture him, received a slight wound in the leg.

Dr. Markoe, who was the son of Dr. Thomas M. Markoe, for a long time professor of surgery in the College of Physicians and Surgeons, was born in New York City in 1882, and was graduated from the College of Physicians and Surgeons in 1885, after which he studied for a time in Munich, specializing in gynecology and obstetrics. Upon his return to New York he became house surgeon to the Sloane Maternity Hospital. He maintained his connection with this institution for many years. In 1890 he became active in the affairs of the Broome Street Dispensary. He was consulting gynecologist to Vassar Brothers' Hospital at Poughkeepsie, N. Y., for a number of years, and was medical director of the Lying-In Hospital from the time of its organization until his retirement in 1917. It was in this institution, which owes its existence largely to him, that most of the work was done on which was based his reputation as an obstetrician. He was a Fellow of the New York Academy of Medicine, the American College of Surgeons, and the American Medical Association, and was a member of various other national, State, and local medical organizations.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, April 2, 1920.

Care of the Soldier.—Care for the physical well-being of the soldier is guaranteed, to a large extent, by the appointment at Aldershot, the big British military station near London, of Major G. E. Cathcart, R. A. M. C., as medical specialist in connection with physical training, feeding and clothing. While it is probable that this appointment is only a tentative measure, it seems likely that it may precede the creation of a soldiers' welfare department of the R. A. M. C. Some need for such a department certainly exists, for although the advice of the medical experts is invariably sought by the physical training and catering staffs of the army, medical men hitherto have had no actual locus standi. During the war the need for a department of this kind was not much felt, as the Medical Corps then contained specialists from London and from all parts of the country, whose advice was always available. Now, however, the army specialist is connected usually with remedial work.

Disabled Officers' Treatment.—In pursuance of the policy of decentralization the British Minister of Pensions has intrusted to the Commissioners of Medical Services in the various regions of the ministry the responsibility of obtaining for disabled officers and nurses the medical or surgical treatment to which they are entitled. A dis-

charged officer or nurse who is claiming retired pay or pension on the ground that he or she is suffering from a disability should also make application to the Commissioner of Medical Services at the Regional office with a view to the necessary treatment being provided. Officers and nurses are advised that in event of making their own arrangements for treatment without the prior approval of the Commissioner of Medical Services of the Ministry of Pensions, it may not be possible to refund to them any of the expenses thereby incurred.

The Problem of Illegitimacy and the State Care of Its Child Population.—It is so obviously a question of the greatest moment to a country that its child population be well cared for, in order that its children may become healthy and well-educated citizens, that it is not a matter for surprise that the State should concern itself with the welfare of the children. It is equally patent that not only has the number of illegitimate children largely increased during the war, but that these should be looked after in the same way as the children born in wedlock are looked after. In Great Britain, from the early Factory Acts up to the last Education Act, the steadily increasing care of the State for its child population can be traced. The problem of illegitimate children is, of course, more insistent than ever before. In 1918, 41,000 illegitimate children were born in England and Wales. Moreover, the number of legitimate births has been steadily decreasing, so that the illegitimates have formed an increasing proportion of the whole. It goes without saying that the fate of these babies is very problematical. At any rate, in this country, their infantile death rate is at least twice that of the legitimate. Again, if one in every five of these infants perishes before it is a year old, the remaining four will in the ordinary course of events, have undergone great risks and some—probably a considerable proportion of the survivors—will have incurred irretrievable injury. It is plain that a high infant death rate signifies a high damage rate. No modern community, and perhaps England in particular, can afford to permit its future workers to grow up enfeebled, puny, and possibly disabled citizens, calculated to become rather a burden than a help to the country in which they were born and brought up. The Government of Great Britain fully recognizes this and realizes its responsibility in the matter and is about to take steps for the relief or betterment of the existing situation. By the instrumentality of Mr. Neville Chamberlain a bill is to be introduced into the House of Commons early in May and which is supported by all the main bodies concerned with the problem. This bill is based upon the principle of increasing and recognizing the responsibility of the father, and failing him, of the State, for the maintenance of the children. Illegitimate children are to be wards of Court and the duty of getting into touch with the father is to be placed upon an official of the Court. The sum payable is to be arranged in accordance with the means of both parents and the real needs of the child. As far as possible the bill will provide for the child to remain with the mother. The bill is a step in the right direction, but is only a small part of the work that must be done if the problem of illegitimacy is to be solved.

The Army Council and the Medical Corps.—In the House of Commons, on March 22, last, in a discussion on the Army Medical Service, Capt. Elliott, a medical M. P. said that the British had lost many thousands of men in the late war because the Army Council had not taken the straightforward advice of the Medical Service. The Medical Corps had made contributions of the greatest value in respect to the treating of the armies in the field. He gave some instances of the indifference exhibited by the Army Council to medical advice. It was impossible to give the young recruit too much to eat. They gave these growing boys 4,000 or more calories a day, and they bolted it up and like Oliver Twist came back for more. The best proof that these recruits did not get enough to eat was the fact that they were willing to spend their own money on food. At the time of the demobilization the physiological experts warned the Army Council that they would have a lot of these young fellows coming back to the camps, and that it would be necessary to increase the rations. But the Army Council took no notice until the Australian troops mutinied and then the Council conceded to force what they had hitherto refused to concede to reason. Another case in point was in regard to the disease known as bilharzia, which attacked the British troops in Egypt. As a result of medical discoveries the troops were rendered practically immune from this scourge, which had existed in Egypt from the time of the Pharaohs. Capt. Elliott strongly urged that the Director General of Medical Services should have a seat on the Army Council.

Typhoid Inoculation.—A very interesting question was asked in the House of Commons the other day, when Mr. Charles Edwards asked the Secretary for War whether between 150,000 and 200,000 uninoculated men served in the British armies in France during the war, whether less than 4,000 of these suffered from typhoid or paratyphoid fever, and whether he attributed the immunity of these uninoculated men to the precautions taken regarding the provision of pure water and food and the measures for the destruction of refuse taken by the Sanitary Services. Mr. Churchill replied that during 1917 there were in France approximately 30,000 men who had not recently, or had never, been inoculated, and during 1918 the number was approximately 70,000. Good sanitation had always had a beneficial effect in checking the spread of the disease. It was also, however, true that the immunity these men enjoyed was due to the fact that there was only a very small proportion of non-inoculated men in each unit.

The Annual Meeting of the British Medical Association at Cambridge.—As mentioned before, the Annual Representative Meeting will commence on Friday, June 25. The session will be continued on Saturday morning, and, if necessary, on the Monday and Tuesday. On the evening of June 29, Sir Clifford Allbutt, after his address as president of the association in the Senate House of Cambridge University will receive distin-

guished foreign guests, and a reception will be given by a local branch of the association in King's College. The sectional scientific meetings will be held in the New Museum on June 30, July 1, and July 2, the mornings from ten to one being devoted to discussions, and the afternoons from two-thirty to laboratory and clinical demonstrations. On the evening of July 1, at 7.30 o'clock, the annual dinner of the Association will be held in the hall of St. John's College, the number at the dinner being limited to 200. Local entertainments, garden parties and those kind of things will be given on several afternoons, and a visit is being arranged to the well-known tuberculous colony at Papworth. July 3, the last day of the meeting, has been set apart for excursions to places of interest in the neighborhood. The various college authorities have offered bedrooms for 1,000 visitors, and to provide them with meals at an inclusive daily charge. There are also a large number of university lodgings in the town, and the local committee will engage as many of these as are needed by visitors.

The Quality of Bread.—The quality of food is of more importance than the quantity, and the need for a properly balanced diet is becoming more and more in evidence and better appreciated by medical men. However, the general public in this country is profoundly ignorant on this matter. For example, nearly all the bread sold in London restaurants, and most people get their meals in restaurants or hotels nowadays, is made from the highly milled variety of flour from which the vitamine content is absent. If whole meal bread or brown bread is asked for, in ninety-five cases out of a hundred neither one nor the other is to be had. The Council of the British Bread and Food Reform League are directing attention to a danger which may arise when bread control is removed. It is pointed out that the competition that will result is apt to lead to the production of articles of very inferior quality unless the Food Adulteration Acts are extended so as to protect meal, flour and bread from deterioration and adulteration. The report of a recent important deputation to members of Parliament draws attention to the fact that ordinary bread is deprived of flesh-forming materials and the substances which form bones and teeth and nourish the brain and nerves, while the vitamines, which are absolutely essential for the maintenance of health, are entirely removed. It may be noticed in this connection that lack of vitamine content does not necessarily characterize a deficiency disease, or rather, lack or absence of the accessory food factors is not the sole deficiency which occurs in certain foods and which, if employed as a regular diet, will bring about a condition of ill-health. Lack of lime salts in a diet will produce certain forms of disease just as surely as lack of the vitamine element, and this fact is beginning to be thoroughly recognized.

Child Poisoned with Illuminating Gas by Its Insane Mother.—Dutiller and Vallée relate the case of an insane woman with persecution delusions who placed a gas tube in the mouth of her two-year-old child and maintained it there for a half hour, long after the child was dead.—*Le Bulletin Médical.*

THE NARCOTIC AND THE REGISTRATION BILLS.

To the Editor of the Medical Record:

Sir: At the hearing on the Cotello Narcotic Drug Bill on April 15 before the Public Health Committee of the New York Legislature, Mr. Kenyon asked if the defeat of his bill for the Annual Registration of Physicians, on the floor of the Assembly on the previous day, was not due to the same form of opposition manifested at the hearing by a few physicians to the Cotello Bill. Both of these bills were endorsed by the Medical Society of the State of New York. In spite of this fact members of the Assembly, Mr. Kenyon said, voted against the bill for Annual Registration of Physicians on the strength of protests received at the last moment from physicians among their constituents.

The Cotello drug bill was frankly endorsed by the State Society to compel the institutional treatment of drug addiction. This measure, if enacted, would compel the physicians of New York State to conform their mode of treatment of these cases to that laid down under this law. Other bills supplementary to this one were the Gibbs bill, giving the right of search and entry to an official of the drug commission to any place where he had reason to believe drugs were kept or patients were treated for drug addiction, and another bill amending the sanitary code of the State permitting local boards of health "to provide suitable places for habitual users of drugs who cannot otherwise be provided for" as well as for those suffering from contagious disease.

It is a surprising fact that a hearing on a bill of such importance to the public and so revolutionary in its effect upon the practice of medicine should practically be unnoticed in the news of the day. Two of the leading morning papers did not refer to the hearing at all, and two others gave only an incomplete report. No mention was anywhere made of the important and unusual fact that the advocates of these drug bills were engaged as public officials either in the public treatment of drug addicts or in the prosecution of those said to be practising in violation of the provisions of the Federal laws relating to drug addiction.

John P. Davin, M.D.

117 West Seventy-sixth Street.

QUESTIONS AS TO SHAVING OR WEARING A BEARD.

To the Editor of the Medical Record:

Sir: In my medical course I remember hearing a European specialist say in regard to shaving: "Gentlemen, if you interfere with nature, you pay for it." But I am unable to find any scientific investigation of the question. I am seeking, therefore, facts and opinions from physicians, and should be grateful if your readers would kindly answer, as soon as possible, the questions below.

1. What are the principal injuries to the skin that come from shaving?

2. What are the general advantages in growing a beard?

3. I believe that the habit of shaving increases neuralgic and other troubles of the face, and tends to lessen the chances of life. Do you believe this, and if so, will you give me any data in your medical practice and experience that would tend to confirm such a belief?

4. Or do you believe the question of shaving, or wearing a beard, from the medical point of view, is not of sufficient importance to merit serious study?

I should be glad if any who feel disposed to reply to these questions would write as fully as possible, and mention any pertinent facts or opinions not covered by the questions.

ARTHUR MACDONALD.

4. Chest Conditions Resulting from War Wounds and Their Surgical Treatment. B. H. Alton.

1. The Medical Aspect of Dental Irritation.—William A. Lurie brings to mind the fact that the removal or the cure of dental infection or irritation does not always cure the patient. Differences of opinion have arisen between the dentist on the one hand, whose interest in a tooth is mechanical, and the doctor on the other, whose interest is physiological. Does the dentist know the seriousness of the patient's harboring an infection while he is attempting to treat and save the tooth? The writer answers the question in the negative. The recent studies in blood pictures have clearly shown the difference in cases where there is found irritation without infection, infection without a vast incident of irritation or both concomitant. The studies of cases of mouth infection and irritation carried on along the same lines show that the same relation holds true with relation to conditions of the oral cavity as elsewhere in the body. In the greatest number of instances dentists who have not had the experience in this direction but who are expert in the mechanical side of their profession, lose sight of these facts. From the medical aspect of the mouth, relative to infection and irritation, the necessity of a proper masticating apparatus is an essential factor, and the one which links medicine and dentistry. The dentist is interested in maintaining a mechanical means for food mastication, while the physician directs his attention to mastication to see that it is properly performed for the purpose of beginning digestion. The greatest effect of mouth conditions is no doubt primarily felt in the alteration of digestion, through the inefficient mechanical construction of the jaws, and second through enzyme activity. An irritation may cause an increase in salivary secretion to such an extent that when food is introduced there is no response to the additional stimulation. Such lack of digestion is recognized as due to a decrease of ferment concentration. An infection may be the underlying factor in the causing of an acid reaction to the mouth sufficient to inhibit the activity of the saliva when it is poured into the mouth. The effect of an oral infection or irritation is not necessarily only a local one, or on digestion entirely. Toxines, as well as bacteria from an infected site in the mouth, are carried everywhere by the blood stream. The numbers of changes in glandular tissue throughout the body resultant therefrom are the subjects of study by many. The effect of the production of energy under the stress of such irritation or infection is being considered in the study of the function of the ductless glands. In such cases the medical view should govern the decision as to the advisability of saving the tooth. Especial attention is directed to the importance of the mouth of a growing child, and of the association of the acute infectious diseases of childhood and dentition.

1. Psychopathies and Neuropathies of Cardiovascular Diseases.—Thomas E. Satterthwaite presents the results of the study of one hundred histories of cardiovascular patients from his office records, selecting those with fairly complete data, and in the order of their filing. The particular problem before him was, in the first place, to discover the interrelation as to frequency between the arrhythmias and the psychopathic states in cardiovascular diseases as they were noted in his records. He used no special classification. From this study one may safely state: 1. Arrhythmias are not active factors in causing psychopathies. 2. Tachycardias are even less so. 3. The incidence of cardiovascular disease in causing psychopathies in general, and in being contributing causes of death in them is from 32 to 35 per cent. 4. On the other hand senile psychoses may be associated in a similar manner with cardiovascular disease in 77 per cent.; psychoses with cerebral arteriosclerosis in 80 per cent. of the cases. 5. With respect to the incidence of such neuropathies as migraine, anginoid attacks, neuralgias, pareses, or paralyses and tremors, his figures put it at 33 per cent. 6. Most of such neuropathies, however, are either incidental or accidental associates of the cardiac or vascular diseases.

1. The Incidence of Acute Rheumatic Fever at Bellevue Hospital.—Alexander Lambert discusses and gives tabulated records of cases of rheumatism admitted to Bellevue Hospital from 1906 to 1919, inclusive, the study having suggested itself as the result of his observation of a surprising diminution in the number of cases of acute rheumatism noted upon his return to the hospital after two years of absence. The figures were obtained in gathering material for a report on health insurance to see whether or not there had been an actual diminution in the number of cases of acute rheumatic fever admitted to Bellevue Hospital, and to see whether any deductions could be drawn from them regarding the wisdom of including dental hygiene in the preventive measures of social insurance. They are too limited for

any sweeping generalizations. But it would seem that the actual and striking diminution of total admissions for rheumatic fever of the past two years was more than accidental, and that for this the dental hygiene more than any other one factor was responsible. That tonsillectomy has also made its impression is most probable, as the diminution of both total number of admissions in the 20 to 29 year group and the percentage ratio to total number of this group is really most striking, especially since during this period of life the liability to rheumatic infection is especially noticeable. The average number admitted of 20 to 29 years of age during the four year period of 1911 to 1914 was 180, while during the five year period 1915 to 1919 it was 110. The ratio to total admissions has also fallen from 17.8 per cent. for 1911 to 1914 to 15.3 per cent. for 1915 to 1919. The two periods from 20 to 29 are the periods in which the figures show most definitely an average reduction of percentage to total, combined with a definite reduction of total admissions. Have tonsillectomies begun to tell, or has it been oral and dental hygiene? Undoubtedly both, as ten years have not elapsed since tonsillectomy before 15 years of age has become widespread, so that it could not previously have affected the older years of this and other age groups in the community.

11. Oxygen Inflation of the Peritoneal Cavity.—Armitage Whitman describes his personal experience with oxygen inflation of the peritoneal cavity, undertaken for the purpose of demonstrating the effect of posture on the internal organs. The experiment was suggested by the observations of Stein and Stewart on the roentgen examinations of the abdominal organs following inflation of the peritoneal cavity with oxygen as an aid to the diagnosis of obscure abdominal conditions. The injection in the writer's case was made by Dr. W. F. Cunningham. He records the experience not for the purpose of discouraging the employment of the method, the importance of which has been already demonstrated, but because he can find nothing in the literature that might lead one to take into account the sensations of the patient. His conclusions from the experiment follow: 1. The experiment was a failure in regard to the purpose for which it was undertaken. In the erect position, the gas once having risen to the subdiaphragmatic spaces, it was impossible to exert sufficient pressure from below to force the liver up and squeeze the gas out. Contraction of the abdominal muscles from below upward also primarily reduced the space into which the gas could escape. 2. The actual injection of the gas was practically painless, and its presence in the peritoneal cavity was attended by none but mechanical disturbances incident to its physical volume. 3. These mechanical disturbances were of such an unpleasant and disabling nature that the method should not be employed without their due consideration. The patients should be warned of what they might reasonably have to expect, and be prepared to spend from three to four days in bed following the injection. In nervous individuals the consequences might be considerably more disturbing.

8. Army Hygiene During the Great War. Sir John Goodwin.

3. Syphilis at a Venereal Clinic.—E. P. Skinner gives an analysis of cases admitted to the clinic of the Royal Hospital, Sheffield, during the period from August 31, 1918, to August 31, 1919, during which time 354 new cases of syphilis were admitted, 329 males and 125 females. He found that primary cases are still in a grave minority of admissions. Women do not seek advice in the primary stage, and steps should be taken to disseminate knowledge of the dangers of venereal disease and the advantages of the clinics among the female population. Continuity of treatment is essential for cure, and discontinuity a possible danger. Only when treatment is commenced before Wassermann reaction has become positive can a cure be definitely promised.

4. A Note on the Later History of Four Cases of Total Laryngectomy.—Sir Charters Symonds reports four cases, three men and one woman, who have lived in comfort and happiness, and who have done useful work, for 8, 12, 15½, and 22 years respectively, after total laryngectomy. These records are of value also in showing the immunity that can be obtained even when the malignant disease is extensive. These people can be understood by those around them by simple lip-movements and the vibration of such an amount of air as can be taken into the mouth and pharynx, while with the speaking tube, which he describes, the patient can be heard in a large room. The immunity in these cases has been largely due, no doubt, to the wide initial removal of structures external to the larynx. The avoidance of preliminary tracheotomy certainly facilitates the operation, and, moreover, diminishes infection. The technique is also a matter of some importance. (The writer may describe this in a later communication.)

3. Note on the Dietetic Treatment of Diabetes Mellitus. R. T. Williamson.

2. The Nature, Prevention, and Treatment of Heat Hyperpyrexia.—W. H. Wilcox, in discussing the *clinical aspect*, gives the results of observations made during the summers of 1916, 1917, and 1918, spent in active service in Mesopotamia as Consulting Physician to the Mesopotamian Expeditionary Force. He made a careful study of the clinical manifestations of the different types of disease due to this cause. Heat hyperpyrexia was the most striking and most dangerous form of illness met with, and this was likely at any period to occur as a complication in the milder types of these effects of heat. After discussing the etiological factors—climate, temperature, cumulative effect of heat, humidity of atmosphere, special rays, night temperature, stagnation of air, dwellings, age and race, alcohol, exertion, water, clothing, constipation, etc.—the writer considers briefly the diseases which predispose to heat hyperpyrexia, among which are malaria, sand-fly fever, the enteric group of diseases, typhus fever, and smallpox. From his experience he had no doubt whatever that heat hyperpyrexia is a clinical entity, occurring apart from intercurrent diseases. The clinical history of cases of pure heat hyperpyrexia and the course of the symptoms after the acute stage, which often exhibit prolonged pyrexia and profound toxemia in the absence of any bacteriological infection, strongly indicate that the cause is an autointoxication as the result of the effect of heat on the body tissues. The autointoxication occurring in heat-stroke was found to be associated with the presence of acetone and diacetic acid in the urine in only a small proportion of cases (about 12 per cent.), and in these the reaction was of only moderate intensity. It thus appears that heat hyperpyrexia is not due to an acid intoxication. The presence of indican in excess in the urine in acute cases is of importance and is an evidence of the autointoxication present. It has been shown by Cramer that beta-tetrahydronaphthylamine will cause hyperpyrexia in animals, and it is likely that similar chemical bodies produced as the result of the effects of heat on the tissues in man may have a like effect. No evidence of bacterial infection was obtained in a numerous series of blood cultures in cases of pure heat hyperpyrexia. Undoubtedly suppression of sweating is a most important predisposing cause in many cases, especially those of heat-stroke or sunstroke. In the writer's cases suppression of sweating did not

always precede heat hyperpyrexia, and though it is an important predisposing factor, it cannot be regarded as the primary cause. In the post-mortem examinations made in Mesopotamia edema and general hyperemia of the brain and leptomeninges were observed, and cloudy swelling of the liver, kidneys, and myocardium was found; petechiæ of the skin and mucous membranes were seen in some cases. No definite signs beyond these were observed more than those indicating intercurrent diseases, such as malaria with enlarged spleen, etc. The clinical types of illness caused by exposure to heat are given as: 1. Heat exhaustion (mild type); 2. gastric type; 3. choleraic or gastrointestinal type; 4. heat hyperpyrexia (heat-stroke or sunstroke).

Heat exhaustion required no special treatment beyond rest, keeping cool, and aperient medicine. The gastric type was dangerous and required great care in treatment. Free purgation, great care in protection from heat, large doses of sodium bicarbonate (30 grains every three hours), and rectal injections of cold solutions of the same salt (2 drams to the pint) gave the best results. The diet in all "heat" cases was chiefly lactovegetarian, the fat and protein being reduced as far as possible. The choleraic type required treatment on the lines of cholera cases, including the injection of physiological or hypertonic saline solution subcutaneously, and cardiac stimulants. Protection from heat was most important.

Heat hyperpyrexia demanded the immediate application of measures to reduce the temperature. Convulsions, which occurred very commonly, were treated most satisfactorily by venesection, 10 to 20 oz. of blood being withdrawn. Cardiac failure was treated by digitalin, strychnine, adrenalin, or pituitary extract hypodermatically. Respiratory failure was treated by artificial respiration and oxygen.

Leonard Hill, in discussing the *physiological aspect*, states that heat stroke results from the rise of body temperature to a height incompatible with the maintenance of the equilibrium of the physicochemical reactions in the cell on which life depends. Such rise may result from inability of the heat-regulating mechanism to control the body temperature under the atmospheric conditions, or from exhaustion of this mechanism. Infection, drink, fatigue, by weakening the mechanism, enhance the risk of heat stroke. The various factors involved are discussed.

Tuberculosis and the Abortive Treatment of Syphilis. Tiéche states that in the latter years of the war both tuberculosis and syphilis increased in frequency. This increase means that more individuals suffer from the associated disease, and the question arises, "Does the abortive treatment of syphilis tend to react unfavorably on tuberculosis?" This naturally leads to the subject of the unfavorable influence of syphilis *per se*, untreated or not, on the companion disease. There is abundant evidence that severe syphilis can light up or aggravate a mild or latent tuberculosis. Infection in well developed tuberculosis does not necessarily aggravate the latter. In fact, there is some experience to the effect that syphilis has been of benefit to tubercle, but to what extent this could have been attributable to the treatment is not certain. The converse is also true, for if today tuberculosis is made worse by syphilis, this aggravation may perhaps be attributed to salvarsan, just as in past years mercury may have been responsible. In view of the different experience the individual can only speak of these matters as he finds them. The author has seen six cases in point in which he was able to follow tuberculous individuals from the time they contracted their chancre. The tuberculosis was in part active and in part latent. In three cases the subjects doubtless were made worse by the neosalvarsan and mercury used by the intravenous route, while two cases of chronic fibroid phthisis were not affected and one glandular tuberculosis was started up anew. Other patients were seen later in the course of syphilis when it was too late to think of abortive treatment. Here intensive antisyphilitic measures appeared to cause exacerbations of tuberculosis in some of the subjects and the author cites two such cases. Here as before chronic fibroid phthisis was not prejudiced. Should one abstain from an abortive or intensive treatment of a tuberculous subject when he contracts syphilis? This is a difficult question, for there are not a few tuberculous who will not suffer from this treatment. Too harsh a ruling might bear unfavorably on mere suspects, for in dispensary treatment one cannot go into refinements of diagnosis. It is in these very suspects, moreover, that some of the worst examples of tuberculosis have followed intensive salvarsan treatment. It is evident that we cannot commit ourselves one way or the other in this problem.

Schweizerische medizinische Wochenschrift.

March 11, 1920, 1, 11.

Encephalomyelitis Epidemica.—Under this name Stahelin describes so-called lethargic encephalitis. As far as known there has been no suggestion of direct transmission. The malady has never been seen during the crest of a grippe pandemic. The disease picture is pleomorphous, so that diagnosis often has become difficult. In the atypical cases a great variety of symptomatology is comprised. A subject with an ataxic syndrome was operated on for cerebellar tumor. Landry's paralysis and other myelitic syndromes have been described. But despite this clinical variability the anatomical lesions in fatal cases appear to be one and the same, and there is no difficulty about the post mortem diagnosis. Several cases are given, one of which appeared soon after eating preserved meat. The symptoms suggested paratyphoid and later after the supervention of diplopia botulism. Of four cases narrated the diagnosis was easy through the presence of the classic triad of fever, somnolence, and diplopia. In a fifth case the diagnosis lay between lethargic encephalitis and apoplexy. By reason of diplopia an eye specialist was consulted, who found myosis and irresponsive pupil, which reacted very slowly to atropine. Complete unconsciousness was followed by death. In other cases the presence of the epidemic led to correct diagnosis. but had the cases been sporadic this diagnosis would at the best have been tentative. An analysis of 17 cases shows that Landry's paralysis and apoplexy may be simulated. By reason of the spinal component the author would introduce the term encephalomyelitis. The undoubted presence of influenza in several cases is placed by the author among the coincidences of disease. Otherwise we must admit identity or at least anatomical correspondence of the two maladies. Or in the absence of a known cause it may be necessary to assume that more than one organism may be able to cause the same clinical affection, and among them the unknown virus of influenza.

Norsk Magazin for Laegevidenskaben.

March, 1920, lxxxi, 3.

Acute Benign Cases of Acanthosis Nigricans.—Bidenkap alludes to the general conception of this condition as one of hyperpigmentation, papillary hypertrophy, and hyperkeratosis. He then describes a case of the benign type not associated with carcinoma. The subject was young, healthy, and vigorous, and without digestive disturbances. The mucosæ were not involved in the pigmentation. Other pigmented affections could be excluded, as arsenicism and Addison's disease. Of a series of 40 cases of acanthosis nigricans on record, one-third were associated with cancer in the abdominal cavity. The author knows of one such case in Norway of this type. The total number of malignant cases known is about 30.

Statistics of Mammary Cancer.—Holst deals with statistics of 81 cases. The axillary glands were normal in 21 and infiltrated in 41, not reckoning the recurrences, which make up the total of 81. The number of cases submitted to radical operation was 63. The number to survive five years without recurrence was 12. Forty developed recurrence within three years. The author's statistics are not cited as a particularly strong argument in support of the operative treatment in all cases of cancer.

Book Reviews.

On Facial Neuralgia and its Treatment. With Especial Reference to the Surgery of the Fifth Nerve and the Gasserian Ganglion. By J. Hutchinson, F. R.C.S., Surgeon to the London Hospital; Examiner in Surgery and the Late Hunterian Professor at the Royal College of Surgeons. New York: William Wood & Company, 1919.

The two hundred and sixteen pages which constitute this volume include the body of the text, an appendix in which a few case reports are given, a bibliography of trigeminal neuralgia and its treatment, and an index. There are thirty-eight illustrations. The author deals chiefly with epileptiform or major neuralgia (tic douloureaux), though one chapter is devoted to a consideration of the other forms, their causes and treatment. The technic of excision of the gasserian ganglion is described and illustrated.

Industrial Medicine and Surgery. By Harry E. Mock, B.S., M.D., F.A.C.S., Assistant Professor of Industrial Medicine and Surgery at Rush Medical College; Attending Surgeon, St. Luke's Hospital; Visiting Surgeon to Washington Boulevard Hospital; Chief Surgeon to Sears, Roebuck & Co.; Fellow Institute of Medicine, Chicago; Lieutenant-Colonel, Medical Corps, U. S. A. With 210 Illustrations. Philadelphia and London: W. B. Saunders Company. 1919.

The ideal of "human conservation and reclamation of all disabled" and methods for the realization thereof are admirably set forth in this volume of 846 pages. The author has considered every phase of the subject, from the rendering of first aid to the Americanization of the foreign employee. Industrial health service, prevention, industrial medicine, industrial surgery, compensation, insurance, medicolegal phases, and reconstruction form the subjects of the six parts into which the text is divided. The bibliography, covering nearly twenty-three pages, gives the literature of the subject since 1916. The index fills twenty-one pages.

The Nose, Paranasal Sinuses, Nasolacrimal Passageways, and Olfactory Organ in Man. A Genetic, Developmental, and Anatomico-Physiological Consideration. By J. Parsons Schaeffer, A.M., M.D., Ph.D., Professor of Anatomy and Director of the Daniel Baugh Institute of Anatomy of the Jefferson Medical College of Philadelphia; Formerly Assistant Professor of Anatomy, Cornell University Medical College and Professor of Anatomy, Yale University Medical School. With 204 Illustrations, of which 18 are printed in color. Philadelphia: P. Blakiston's Son & Co. 1920.

In view of the fact that the study of anatomy has not reached a state of finality and that the anatomical field has not been fully gleaned of its harvest, this volume is a particularly valuable addition to the literature of the subject. The author, as he states in his preface, has aimed to present a more or less comprehensive account of personal studies and observations on the genesis, development, and anatomy of the nose and its related parts, rather than to compile a fairly voluminous literature with its not infrequent diverse conclusions. Whether approached from the embryological, anatomicophysiological, otorhinolaryngological, or other point of view, this clear discussion of the author's researches and findings must prove interesting and valuable. The volume comprises twelve chapters, covering 370 pages, eleven of which are devoted to the index.

Dr. Crawford W. Long. The Distinguished Physician-Pharmacist. By Jos. Jacobs, Phar. D., Atlanta, Ga. 1919.

The full title of this little pamphlet is "Some Personal Recollections and Private Correspondence of Dr. Crawford Williamson Long, Discoverer of Anesthesia with Sulphuric Ether, together with Documentary Proofs of His Priority in this Wonderful Discovery." It is perhaps not generally known that Dr. Long, with his brother and a Dr. Billup, operated a drug store in Athens, Ga., opposite the campus of the local university in 1851, where the biographer was later employed as a apothecaries' apprentice. Dr. Long's office was in the rear of the store, and he practised both medicine and surgery. The recollections of Jacobs do not apparently go back of 1875, and Dr. Long's death took place three years later. While the main facts of his life and activities, including the discovery, are well known, the author is able to add many details from first or second hand information. The purport of the booklet is in part to focus attention upon the fact that Dr. Long was a pharmacist as well as a medical man.

Mind and Its Disorders. A Text-Book for Students and Practitioners of Medicine. By W. H. B. Stoddart, M.D., F.R.C.P., Lecturer on Mental Diseases to St. Thomas' Hospital Medical School; Examiner in Psychology and Mental Disease to the University of London; Honorary Consulting Physician in Mental Disease to the War Office; Honorary Treasurer of the British Psychological Society, and of the British Psycho-Analytic Society; Late Resident Physician and Medical Superintendent of Bethlehem Royal Hospital. Third Edition, with Illustrations. Philadelphia: P. Blakiston's Son & Co. 1919.

The study of the subconscious by psychoanalytic methods had become sufficiently important to justify the author of this volume in adding two chapters bearing on this subject in the second edition. Since that edition appeared, he states in the preface to the present edition, he has fundamentally changed his attitude toward mental disease, having personally investigated very many patients by the psychoanalytic method and thus been convinced of the truth of Freud's doctrines. He now holds that mental disease can be understood by studying the psychology of the unconscious mind of patients, and that the physical manifestations of a functional nervous disorder must be regarded as secondary, not primary, as he taught in the first edition of this work. The classification has been completely remodelled, and new chapters have been introduced on "The Anxiety Neurosis" and "Paraphrenia." Some chapters have been entirely rewritten and others enlarged. The author does not credit the war with having added much to the knowledge of mental disorder; it has stimulated interest in functional nervous diseases, but, so far as he is aware, none of the war cases underwent a deep psychoanalysis. The text is arranged in three parts, devoted, respectively, to normal psychology, the psychology of the insane, and mental diseases, the major portion of the book being devoted to the last.

Leçons de Pathologie Digestive (Quatriéme Série). Par M. Loeper. Professeur agrégé à la Faculté de Médecine de Paris. Médecin de l'Hôpital Tenon. Paris: Masson et cie, 1919.

The subject of these lectures are as follows: precocious pains of digestion; hypergenetic gastritis; pyloritis; toxic gastritis; dyspepsia of commotional origin, etc.; gastric symptoms of biliary origin; sarcoma of the stomach; gastric perforation; duodenal ulcer; bacillary periphrenitis; bacillary dysentery; anemias; cardiac failure; enteroneuritis; persistent celialgia; pain in cancer of the colon; typhlotomy following typhoid fever; premonitory diarrhea in malarial attacks, etc. The motif of these lectures appears to have been the rich military material of the latter years of the war with the more occult causes of indigestion found by the author. The book seems to be a contribution of merit to gastroenterology.

Einige Erfaiirungen über die therapeutische und diagnostische Bedeutung der Milchinjektionen besonders in der Ophthalmologie. Von Gerda Uddgren, Med. Lic. Stockholm: Ivar Haeggströms Bogtryckeri, 1918.

This brochure of 165 cases is devoted largely to a tabulation of cases there being twelve separate tables of diseases of the eye treated by milk injections. This is followed by an analysis of the case material, the biology of milk injection, condensed summaries and a bibliography. The conclusions are not very illuminating. Therapeutic action does not depend on fever induced at times by the injections. In certain cases the disease process is rendered more acute by the latter. Sterile and nonsterile milk are not essentially different in their action. Sterile milk can induce fever.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held January 8, 1920.

DR. CHARLES H. SMITH IN THE CHAIR.

A Case of Complete Heart Block.—Dr. WILLIAM ROSENSON presented this patient, a girl 10 years of age, who first came under his observation at Mount Sinai Hospital two years ago, at which time she had a pulse rate of 44, but was perfectly comfortable, her only complaint being slight pain and distress over the precordium on considerable exertion. Her family history had no bearing on her condition, save for the fact that a sister had mitral regurgitation. The patient's personal history showed that labor had occurred at full term and was tedious and difficult, and that she had been blue for several hours after birth. She had had pneumonia, diphtheria, and whooping cough, but no chorea, acute rheumatism, or pains in the joints. She showed no symptoms of heart trouble until she was seven years of age, when she first complained of pain and distress over the precordium, but there were never any signs or symptoms of decompensation. Physical examination revealed a definite apical impulse in the fifth interspace somewhat outside the mid-clavicular line. Percussion showed the right border of the heart 5 cm. to the right and the apex 9½ cm. to the left of the mid-sternal line. There was a long sawing diastolic murmur, transmitted over the precordium, best heard in the second left interspace. The pulse was always between 40 and 50. The electrocardiograph showed complete heart block. The heart was enlarged both to the right and to the left; the heart function, however, was quite normal. There was absolutely no cyanosis, but slight dyspnea after hopping one hundred and fifty times. The blood and urine were normal. The fluoroscopic examination showed a typical condition which the roentgenologist stated was characteristic of heart block. There was a coincident contraction of the right and left sides of the heart. He thought the murmur was congenital on account of its character and the history of the case. The defect, though impossible to locate definitely, seemed to be a direct communication between the aorta and the pulmonary artery, just above the aortic valves. Dr. Rosenson said he had been able to find only six cases of congenital and twenty cases in all of heart block in childhood described in the literature. Some of the reported cases were due to diphtheria and rheumatism.

A Case of Auricular Fibrillation in a Young Girl.—Dr. ROSENSON presented this patient, a girl 15 years of age. He stated that she gave a history of having had pneumonia twice and frequent attacks of tonsillitis. She gave no history of rheumatic pains or joint involvement. Seven years ago she was in the wards of Mt. Sinai Hospital, suffering from symptoms of decompensation, dyspnea, and palpitation. During the past five years she had attended school regularly, was comfortable all the time, and had never been compelled to take to her bed. About a month ago she had slight pain over the precordium, and considerable dyspnea in walking up stairs and passing into the different class rooms at school. She had an absolutely irregular pulse, the rate being 120. A definite impulse could be seen in the mid-clavicular line. On auscultation a blowing systolic murmur at the apex could be detected, and she was in bed ten days on large doses of digitalis. She had had an irregular pulse only during the past month, though there was evidence that she had had heart disease for ten years. The electrocardiograph showed auricular fibrillation and the *x*-ray showed the heart to be enlarged.

A Specimen of Congenital Heart Malformation.—Dr. WALTER LESTER CARR presented this specimen. He stated that the boy from whom it was taken was 12 years of age, undeveloped and poorly nourished; both skin and mucous membranes were markedly cyanosed. The fingers and toes were clubbed with capillary pulsation. Venous pulsation was seen on both sides of the neck. The chest was not rachitic, but there was a flare in the costal cartilages from the seventh to the tenth ribs on both sides. The heart showed a diffuse heaving, without a distinct apex area. Palpation gave a thrill over the entire precordium. Auscultation revealed an intense systolic murmur with the first sound, heard with great intensity at the second left interspace, and with diminished intensity in the back. The difficulty was to determine the relationship of the murmur, but finally the diagnosis was made that there was a patent foramen and an obstructed pulmonic valve. The heart was hypertrophied. Changes were detected in the lungs. This was confirmed by the *x*-ray, which showed the heart enlarged and the lungs infiltrated. The child had no edema and the urine was negative. The temperature was irregular, owing to the lung condition. The blood showed an increase in the red cells to 6,900,000. The child was allowed around the ward, but gradually grew worse, the tuberculous process in the lung increased, until he had to be kept in bed and finally died on November 30, 1919. In showing a specimen of congenital heart malformation it was well to appreciate that there might be a defect in development that gave congenital heart disease or there might be heart disease, as endocarditis, develop in intrauterine life. This specimen belonged to the type of defective development. Clinically one had to consider (1) the character of the lesion, (2) the prognosis, and (3) the likelihood of intercurrent disease. First, as to the character of the lesion, a patent foramen or an obstructed pulmonary artery might usually be detected without difficulty, but in the malformation shown a decision as to the complete lesion was difficult. Second, the prognosis was always bad, as the child could not develop and grow, since the heart was not able to carry on the circulation. Third, pulmonary tuberculosis was likely to occur.

Drs. CORNWALL and WEISS had performed the autopsy, under the direction of Dr. Larkin of the Strecker Laboratory. Their report showed that the heart was considerably enlarged. The myocardium was beef red in color and presented no evidence of interstitial fibrosis. The valvular arrangements in the heart were of a very peculiar nature. The pulmonic orifice was considerably narrowed. The semilunar cusps of the valve were misplaced, being about an inch and a quarter above their normal level. There were several redundant folds of intimal endothelium between the conus arteriosus of the right ventricle and the true semilunar valves of the pulmonic. These intimal folds were arranged in the form of pseudo valves. The left ventricle was considerably widened and showed three sets of valves, those from the right heart, namely, the tricuspid, and those from the left heart, namely, the mitral and the aortic. The mitral valve was posterior to the tricuspid and somewhat to the left. This arrangement was made possible by the absence of a portion of the intraventricular septum. The foramen ovale was widely open. The aorta presented no anomalies. The ductus Botalli was patent half way across. A probe could be passed half way across from the aortic to the pulmonic artery, but not straight through. The conditions in the heart were pulmonary stenosis; patent foramen ovale; patent intraventricular septum, eccentric hypertrophy of the left heart, and slight concentric hypertrophy of the right heart. The circulation then would permit of a three-fold distribution of the right auricular blood, namely, most of it would enter the left ventricle, and lesser amounts would enter the right ventricle and left auricle. The absence of a marked hypertrophy of the right ventricle in the face of pulmonic obstruction was to be explained, it seemed, on the basis of a great percentage of the blood passing in two directions, in addition to the normal. Incidentally it might be noted that this might account in no small measure for the intense cyanosis observed during life. In addition to the heart defects, the autopsy revealed a diffuse miliary tuberculosis, and amyloidosis of the liver, spleen, and kidneys.

Dr. WILLIAM I. REARDON said there was really nothing to be added to what Dr. Carr had said. In connection with the left ventricle there were three valves, the tricuspid, aortic, and mitral, while with the right ventricle there was only one, the pulmonic valve, which was markedly stenosed. There were two patent areas in the intraventricular septum. The circulatory

feature of interest was that the right ventricle received its blood for the pulmonary circulation by an overflow from the left ventricle through the patencies in the septum. There was an abortive attempt at a patent ductus arteriosus Botalli, a small sac-like depression being present in the pulmonary artery and also in the aorta, but a probe could not be passed through connecting these up. The foramen ovale showed a small patency.

Dr. MURRAY H. BASS read this paper, in which he stated that the development of the electrocardiograph had opened up a vast field for exploration of both normal and pathological conditions of the heart, and by means of this information they were able to group the various cardiac irregularities in a much more scientific manner than formerly, and had brought out the fact that cardiac arrhythmias were really not as rare as had previously been supposed. Dr. Bass reviewed the various types of arrhythmia which were met with in childhood, laying special stress on the prognosis connected with each variety. These types were: (1) Sinus arrhythmia; (2) simple tachycardia; (3) paroxysmal tachycardia; (4) auricular fibrillation; (5) heart block; (6) premature beats. Sinus arrhythmia, he said, was by far the commonest form of juvenile irregularity. This condition rose from changes in the vagus impulse, which resulted in the heart as a whole beating at different rates at different times. Very marked varieties of sinus arrhythmia might perhaps be considered as bordering on the pathological, but this type of irregularity was found in practically all children, so that it was spoken of as a physiological irregularity. It was very important to bear this fact in mind, since many parents had been unduly alarmed by being told that their children were suffering from heart disease when in reality the condition present was only sinus arrhythmia. In diagnosing this condition the child should be asked to take deep breaths, when the irregularity at the pulse would be brought out more clearly. Following this the child should be asked to take some rapid exercise, when the irregularity if due to sinus arrhythmia would diminish or entirely disappear. As a final test, though this was rarely necessary, atropine might be administered, following which the irregularity would disappear owing to the blocking of the vagus impulses. This condition needed no treatment *per se*, though when present in high-strung neurotic children it should be regarded as one of the evidences of nervousness, and the appropriate treatment of the condition instituted. Under no circumstances should exercise be forbidden on account of the heart irregularity alone. Under the head of simple tachycardia were included all those cases of rapid heart in which the pulse tracings or electrocardiogram revealed no abnormality of the heart mechanism except increased frequency of the beat. These cases differed from paroxysmal tachycardia in that the electrocardiogram showed the impulse in the heart to rise at its normal site of origin, whereas in paroxysmal tachycardia the impulse arose elsewhere. Simple tachycardia might result from nervousness, hyperthyroidism, or from conditions in the heart muscle itself making increased demands on the circulation. It was associated with fever and certain disturbances of nutrition, such as scurvy. In rare instances tetany might be the cause of tachycardia. Paroxysmal tachycardia was a condition characterized by sudden attacks of very rapid heart action, in which the electrocardiogram showed that the impulse during the attack failed to arise in the sinus node, but originated in some other portion of the heart tissue. The cause of these attacks was not at all clear. Some of the cases occurred in previously healthy children; others were found in children suffering from rheumatic carditis or diphtheritic myocarditis. Contrary to the condition in adults, the great majority of cases in children occurred in individuals free from valvular disease. It might occur at any age, the youngest reported case being 28 months old. The attack started very suddenly, accompanied by an abnormal sensation in the heart region, occasionally by vomiting and depression. It was quite remarkable to see how comparatively comfortable these children were even when the pulse rate lay between 200 and 300. In addition to the rapid pulse there was excessively rapid pulsation at the wrist. The duration of an attack might vary from a few hours to several weeks. Not enough cases of tachysystole had been carefully observed to permit one to speak with any degree of positiveness as to the prognosis. If the attacks did not occur with great frequency, and if the heart muscle did not seem much affected, the outlook as to life was apparently good, since many of the cases were reported in adults who had survived, though their attacks began in childhood.

Auricular fibrillation was infrequent in childhood, and its characteristics when present in early life did not differ in any way from those found in adults. The reason it was rare in childhood was because it almost never occurred in a heart previously healthy.

Heart block in children, contrary to the condition in adults, was due to the acute rather than to the chronic cardiac diseases. Whereas the common causes in adults were syphilis and arteriosclerosis, in children acute rheumatism, diphtheria, and less often pneumonia were the chief etiological factors, though it might less commonly be due to congenital malformation. Too few examples of heart block had been examined and followed up for one to be able to say much in regard to their prognosis. They undoubtedly must be looked upon as very serious cases, and especially when accompanied by defective cardiac development should call for a very guarded prognosis.

Premature beats were not a very frequent finding in childhood. While in adults they were of no very harmful portent, in childhood they were often an indication of severe damage to the heart muscle. There was considerable difference of opinion as to the prognostic significance of extrasystoles. Personally he could truthfully say that he had never observed extrasystoles in children except in cases in which he could put his finger on a real cause for serious heart damage. Thus he had seen them in the course of diphtheria, and had seen them persist for several years after an acute illness.

In summing up, Dr. Bass said the fact should be emphasized that, contrary to the views entertained five or ten years ago, the cardiac arrhythmias were not confined to adult life. Moreover, practically all the various forms of irregularity were represented in early life. It was also of considerable interest to note that the same clinical conditions might have an entirely different etiology in childhood and in adult life. On the other hand, he did not wish to convey the idea that arrhythmias were commonly encountered during childhood; he believed, however, that they were of frequent enough occurrence to be of considerable clinical importance. Now that most of the larger hospitals were equipped with electrocardiographs, he thought that pediatricians should make an effort to examine all cases of cardiac arrhythmia cardiographically in order that their knowledge of this relatively new and unexplored field might be rapidly increased.

Dr. LOUIS FAUGERES BISHOP said he had had the privilege of following one of these examples of congenital heart trouble for quite a number of years. This patient had had a very slow heart from birth, and her father, being an army surgeon, she had been kept under close observation. At one time her condition underwent a sudden deterioration and Dr. Bishop was consulted. He found that she had a heart rate of about 40. The Mackenzie polygraph (at that time they did not have the electrocardiograph) showed evidence of auricular flutter superimposed on the congenital heart block and that explained why she was not in as good condition as ordinarily. The auricular flutter subsided, and she regained her normal health. She had since married and gone through a confinement safely, and was enjoying a fair degree of health.

Dr. HERMAN SCHWARZ stated that he had followed up the cases of three children who had presented extrasystoles. One was a child, 4 years old, whom he only saw for a few months. The second child was 9 years old when Dr. Schwarz first saw him, four years ago. The third was 7 years old, two years ago. There had never been any acute disease and there was no etiological factor obtainable. These children were not sick, and did not show any signs of cardiac distress. It would seem that extrasystoles, associated with other heart lesions, might mean a diseased ventricular wall. Perhaps this was also the case where there were no

other lesions. However, the same care should be taken at the start in these cases as though they were straightforward valvular disease of the heart.

Dr. CARR spoke particularly of tachycardia. He stated that he had recently seen a nervous boy who was away at boarding school and often took more than ordinary exercise. An *x*-ray showed the heart of normal outline, and after exercise the heart rate was regular and steady. An irregular, rapid heart during the time of development and growth was not at all unusual. It was unfortunate that terms were used that gave the impression that these heart conditions were organic. Physicians were responsible for insisting that rapid and irregular hearts should be cared for as serious lesions, whereas regulated exercise lessened the rapidity and irregular action. He had seen some children and babies with acidosis in whom the action of the heart was rapid. One baby was a year old and had a pulse rate of 190, and a decided acidosis without organic changes.

Dr. WILLIAM ROSENSON expressed the opinion that it was not possible to say anything definite in regard to the prognosis of extrasystoles. In some cases of extrasystole there was serious damage to the heart, while in others there were neither symptoms nor signs of cardiac disease. In two such cases coming under his observation the extrasystoles disappeared from time to time, then again they would appear. The cardiac function was good and sometimes the systolic murmur was heard only over the pulmonic area. In neither case could he say anything in reference to prognosis from the extrasystole alone.

Dr. DEVER S. BYARD stated that his impression was, generally speaking, that extrasystole did not necessarily express a serious cardiac condition, although he had not noted it very frequently in children. He recalled extrasystole in two brothers in immediate convalescence from severe measles. One boy was very ill, his measles being complicated by double otitis media and acute endocarditis. He showed extrasystole on the twelfth day, following the appearance of the rash. The younger boy also had a severe type of measles, with no apparent complication. On the tenth day following the appearance of his rash, he too showed extrasystole. The extrasystole in the boy having the endocarditis persisted nearly four weeks, but in the second case it disappeared after three weeks. Both subjects had some circulatory embarrassment in the first week. Electrocardiograms gave no other evidence of cardiac disease. In the one child the evidences of the endocarditis persisted nearly three months. In the other, after the first week the extrasystole was the only abnormality noted. Both boys were now absolutely free from evidence of cardiac disease. These probably instanced cases presenting extrasystoles in toxemias, in some of which, at least, the symptom need not be regarded as particularly unfavorable.

Dr. ROBERT H. HALSEY called attention to several outstanding facts in the history of the introduction and use of medical instruments. First, the introduction of the clinical thermometer brought out a good deal in reference to the occurrence of temperature which had not been thought of before; but most important, temperature was only a symptom, especially in infectious diseases. When the sphygmomanometer was introduced, trouble began in the effort to know what high and low blood pressure meant. Even now many failed to realize that it was only a symptom. So, too, with the introduction of the electrocardiograph, there were a number of things that were not yet understood, and one of these was the extrasystole. One interpretation was that the extrasystole indicated an irritable state of the heart muscle, and depended upon a condition which might be temporary or progressive and permanent. Other signs must be considered with the extrasystole, and thus together they might indicate slight or serious changes taking place.

Dr. L. T. LE WALD said that during a discussion before the Section on Medicine a few months ago the *x*-ray was referred to as one of the older methods like auscultation, so perhaps he was a little out of date in speaking of the *x*-ray, though the *x*-ray was only twenty-five years old. However, though the electrocardiograph had come largely into use in the diagnosis of heart conditions, the *x*-ray evidence was still of extreme value. He had known such a gross lesion as dextracardia missed by the electrocardiograph examination in the absence of *x*-ray examination. He wished therefore to enter a plea in regard to the interpretation given as to the size of the heart, since a slight alteration in the position of the patient might materially alter the diameters of the heart. He had seen such gross errors with plates taken on the back of the patient, and in children who were ill; that was apt to be the case, as it was easier to take the plate that way. Unless one realized the possibility of gross deformities in the shape of the heart when the plate was taken on the back, one might be led into error. It was a difficult problem to establish a standard for the normal size of the heart at different ages, and particularly was that true in children. The effect of the respiratory phase on the size of the heart was very marked and the difference between a plate taken in the upright and one taken in the prone position was 10 or 15 per cent. There was also difficulty at times in distinguishing between right and left side enlargements. To obviate the possibility of error due to these different positions, one should put markers on the front and back of the chest to make sure that there was no rotation at the time of the exposure. Another very important point, especially applicable to difficult cases in which one was trying to discover minute changes, was the advisability of making a series of shadows at a long distance and then averaging the results. The civil engineer employed this method of taking averages when he was endeavoring to make accurate calculations, and it was certainly wise to use such a method in this work.

Dr. CHARLES HENDEE SMITH said he was interested in the remark that mothers ought to be taught not to worry about these irregular hearts, and also felt that too few doctors realized that these irregularities were not of serious significance. Nurses were perhaps in greatest need of education on this subject. If a child had an irregular heart and stimulants were left about the nurse was sure to give them. Premature systoles, in his experience, were very rare; he remembered seeing only three cases of this condition. He recalled one child, otherwise normal, who from time to time came with fairly frequently extrasystoles. The other cases that he had seen had a moderately severe heart lesion, and had all done perfectly well. It certainly was a rare condition in children whose hearts were damaged and decompensated. He was surprised to hear that Dr. Bass had found it to be considered more serious in children than in adults.

Dr. BASS, in closing, said he was glad his paper had provoked some discussion about extrasystole, because in looking up the subject in the literature he had found so many different opinions expressed. He had not seen a great many cases, and those he had seen seemed to follow serious conditions. The statement about extrasystoles being more serious in children than in adults, Dr. Bass said, was quoted, the statement having been made by Dr. Wilson in an article in the *American Journal of Diseases of Children*, published two or three years ago. From the standpoint Dr. Halsey had taken he must be correct. These cases should be kept under observation and reported on from time to time. Statements made in the literature regarding extrasystole were very vague and misleading. Most of these cases were reported as cases of patent ventricular septum and he had thought that his case might be explained on that basis. The *x*-ray findings were of considerable interest. Cases of patent ventricular septum, when examined by means of the fluoroscope, showed the heart shadow to be circular in outline. The contractions of both the right and left heart borders occurred synchronously, so that the shadow appeared suddenly to diminish in size with each systole. This was probably explained by the fact that there was some rotation of the heart, resulting in the right border being formed by the right ventricle (instead of the auricle) and the left border by the left ventricle.

Dr. BISHOP said that in the girl with heart block shown this evening there were two ventricular beats. The impulse normally came down into both ventricles at the same time. In cases of heart block there was often a double beat of the ventricle, as the impulse started in one ventricle which contracted first.

Dr. SMITH asked whether in paroxysmal tachycardia anybody had tried vagus pressure. He stated that he had seen one elderly person and one adult, who by pressing on the transverse process of the cervical vertebra, could control the paroxysmal tachycardia.

Dr. HERMAN SCHWARZ said that Dr. Koplik had observed a case of paroxysmal tachycardia for many months in the wards of Mount Sinai Hospital, and that pressure on the vagus did not cause any change in the rhythm.

Fluid Injections in Dehydrated Infants.—Dr. STAFFORD MCLEAN read this paper, in which he described animal experiments made during the summer of 1918 for the purpose of securing exact data on the effects of the introduction of fluids in dehydrated infants, and reported on a series of dehydrated infants treated by fluid injections. Experiments were made in rabbits, using 4 and 6 per cent. sodium bicarbonate injections intraperitoneally, and also injections of 6 per cent. dextrose, which led them to the conclusion that similar injections could be given to infants without causing injury or discomfort. For the series of infants thus treated charts were kept in the wards, in conjunction with the ordinary ward records, upon which were recorded the immediate effects of fluids injected; these included weight taken before injection and twenty-four hours later, and records of pulse, temperature, and respiration one-half hour before and one hour after treatment. Only infants showing signs of dehydration were treated, there being 76 infants who received in all 269 injections of fluid. Of these injections 155 were hypodermoclyses, 92 were intraperitoneal, and 22 were sinus injections. The mortality in these 76 cases was 56.5 per cent. The amount of the clyses varied between 90 and 150 c.c., depending upon the size and condition of the child. The following different solutions were used: 6 per cent. dextrose in normal saline, 6 per cent. dextrose in distilled water, normal saline solution, 2 per cent. sodium bicarbonate with 2 per cent. dextrose solution, and 1 per cent. dextrose with 1 per cent. sodium bicarbonate. No bad results had been noted from the intraperitoneal injections except discomfort in a few instances. An analysis of the 76 cases showed that there were 26 cases of acute intestinal intoxication, or 34.2 per cent.; of all other diseases there were 50 cases. The mortality in the intestinal intoxication cases was 76.9 per cent., as contrasted with 52 per cent. in the other diseases. The essayist gave a detailed analysis of various groups in this series of cases, showing the effects of the injections upon weight, temperature, and respiration at different ages, and summarized his results as follows:

"Injection of fluid into the peritoneal cavity in dehydrated infants is a simple method of procedure, and in our hands has had no undesirable effects. The size of the infant is no bar to his ability to utilize the fluids injected. From the results of injections in very small infants, under 3000 grams, we are led to believe that larger infants might utilize larger amounts than have been given the infants in this study. Age has no bearing on an infant's ability to *utilize* injected fluids. The pulse is more frequently affected after sinus and intraperitoneal injections than after hypodermoclyses. The respiratory rate is more frequently affected in peritoneal than in sinus injections and hypodermoclyses. The temperature is more frequently elevated in sinus than in intraperitoneal injections or hypodermoclyses. Weight gains were more frequently noted following intraperitoneal injections than after sinus injections or clyses. Certain infants do not show any improvement until they have had repeated injections of fluid. The shorter the interval between the onset of symptoms and the beginning of treatment the greater is the response."

Dr. HERMAN SCHWARZ expressed the opinion that this was a very important contribution to the study of water balance in infants and children, a question which was gaining more and more importance. and rightly so. Through an understanding of water balance the increased infant mortality might be explained and also the occurrence of acidosis in gastrointestinal and other diseases. It was also important in regard to the fever itself. In new-born infants fever had been thought to be due to lack of food, but the late Dr. Crandall showed that it was due to lack of water and not lack of food. Meyer took three groups of children and gave them a protein milk of high concentration, containing about 1,200 calories per liter. The water intake was very much reduced. The first group lost weight; the second group held its weight, and the third group gained for a little while. The first group, that which lost weight, also regularly showed a rising temperature. This fever could be made to disappear by giving the children water, and they could also be made to gain merely by the addition of water. The nitrogen balance was positive, but the sodium chloride balance was negative. J. O. Balcar's experiments (*Archives of Internal Medicine*, Volume 24, No. 1, p. 116) also showed that if animals were given large doses of sugar, temperature could be produced, but if large doses of water were given in addition, the temperature could be brought down. Many children had increased temperatures during the summer, without anything accountable for them. These temperatures might go up as high as 101° or 101.5° F. and could be made to disappear by absolutely no other procedure than the giving of fluid. The amount of fluid excreted by a child in hot weather was about six times as much as in cool weather. In sick infants, especially those with gastrointestinal conditions, acidosis and the like, it was important above everything else to make sure that the water balance was amply covered with a normal or even more than a normal amount of water, wholly apart from the calories ingested.

Dr. SMITH stated that those who attended the joint meeting of the Pediatric Societies in Philadelphia would remember that at the Children's Hospital they gave fluid by mouth in the long intervals between feeding. They had been trying this at Bellevue Hospital, administering the fluid by means of a catheter and funnel. The fluid was given during the long interval between feedings at night. By this method one could give a good many ounces of fluid in twenty-four hours. It was interesting that in the case of one or two children who were being fed on thick gruel because they did not retain liquid food the water administered in this way stayed down better at night. Giving water by gavage had the advantage that it did not require the complicated apparatus for sterilization as in other complicated methods of administration. A child would often retain water given by gavage when it could not retain it if it was given with the food.

Dr. HAROLD RUCKMAN MIXSELL stated that at the Nursery and Child's Hospital they had combined two methods of giving fluid, giving ten ounces of glucose and normal saline, and they felt the mortality had been reduced by this combination. The combination of glucose and physiological saline solution was used elsewhere, but he felt it ought to be mentioned in connection with this paper.

Dr. L. T. LE WALD mentioned that in connection with the new method of *x*-ray examination after injecting oxygen into the peritoneal cavity for diagnostic purposes the possibility of untoward consequences had been brought up. Dr. McLean's experiments were very valuable as showing that this procedure was devoid of danger. Owing to the fact that the injection of air into the peritoneal cavity was of such great diagnostic value a contribution that went to show that the procedure was devoid of danger was most welcome.

Dr. MCLEAN stated that he was familiar with the work of Dr. Ludwig Meyer to which Dr. Schwarz had referred. In the study just made he had been careful to avoid conclusions. Dr. Mixsell in discussing the paper made some remark about Dr. Marriott's method of treating dehydration; he knew of that work but it was not being done at the Babies' Hospital. In reference to Dr. Le Wald's remarks, it was extremely difficult to puncture the intestine when one tried to do so and thus far he had had no accidents. In a couple of Dr. Blackfan's cases where this method had been used just prior to the infant's death a small hemorrhagic area had been found about the site of the puncture and in other cases under the same conditions some fluid had been found in the peritoneal cavity. Although this method was used successfully in a number of cases by Dr. Blackfan he had stated in his letter that Dr. Howland had brought the method back from London where he had seen it used in one of the hospitals.

Stated Meeting, Held February 12, 1920.

DR. CHARLES H. SMITH IN THE CHAIR.

Encephalitis Lethargica.—Dr. STAFFORD MCLEAN presented this patient, a female child, 3 years of age, admitted to the Babies' Hospital, January 31, 1920. The family and personal history of the case were of no interest. Up to January 27 this child was entirely normal. At that time the mother noticed that the child was drowsy and refused to take food, but was otherwise normal. On the following day the drowsiness increased and she stopped talking and crying. The child's condition remained the same until she was brought to the out-patient department on January 30. The child walked in and the writer remembered seeing the mother and child walk down the street after the clinic. The mother stated that the child had not vomited and had had no fever. The child was admitted to the hospital on January 31 and had been there for the last thirteen days, during which time her condition had changed but little except for increasing drowsiness. There had been some slight improvement. She had had no convulsions. On the day of her admission, which was the fifth day of her disease, she was unable to walk; when placed on her feet she had a tendency to fall backward and to the left. She responded by a slight cry to painful stimuli, but not in the way that a normal child did Physical examination showed a well-developed child with mask-like facies. She was somnolent, and all movements were accompanied by a coarse tremor. There was some catatonia. The child could move the extremities at will, but such movements were accompanied by tremor. The knee jerks were increased. There was no opisthotonos. The child had not spoken since she had been in the hospital, though she cried occasionally. The condition was not tuberculous meningitis, brain tumor, brain abscess, or polioencephalitis. The child was fed by spoon and gavage. The spinal fluid was examined twice, and found negative both times. The von Pirquet was twice negative. The eye grounds were negative. The urine was negative. The white blood corpuscles numbered 10,000, the polymorphonuclears being 66 per cent.

Dr. FRANK J. BEVAN said that when the child first became ill the mask-like expression was more decided than during the past three or four days. The child now cried and had some expression, which was regarded as evidence of improvement. During the first ten days they had used gavage, but during the past four days this had not been necessary, so they felt that there was a tendency toward recovery.

Dr. SMITH said they had had two such cases that recovered, and apparently the children who recovered were just as sick as those who died. They had had three or four cases of encephalitis lethargica at one time. The children presented a picture strikingly like that of tuberculous meningitis.

Dr. MCLEAN said this was the third case they had had. The other cases were one and two months old. The earlier case had been in the hospital six or seven months ago, and he had had a letter from the mother, stating that the child was entirely normal except for a "weakness of the back." In reply to the question as to how he would confirm the diagnosis of encephalitis lethargica, Dr. McLean said it was a very difficult matter to make a diagnosis in these cases, and he had arrived at a diagnosis largely by exclusion. It was not a tuberculous meningitis because the von Pirquet was negative, and the spinal fluid had no tubercle bacilli. It was not a brain abcess because there was no vomiting. The onset was too acute for a brain tumor; if it were an abscess fever would be present and the blood count would be different. The onset did not suggest a polioencephalitis, nor did the spinal fluid findings, and the lethargic state had lasted too long. Hence he had put the case under encephalitis for the lack of a better group. In reply to the question as to how the child was being treated, Dr. McLean said the only thing they were doing was trying to keep up the nutrition.

Dr. ELIAS H. BARTLEY said it was unusual to find a normal spinal fluid in these cases. He had usually found an increased cell count, but it did not correspond to that of tuberculous meningitis. At times it was difficult to make a differential diagnosis between this disease and the cerebral form of poliomyelitis. While it was unusual to find a normal cell count in encephalitis lethargica, he had no criticism of the diagnosis.

Dr. SMITH said some of these cases had an increased cell count, but again some did not. It was interesting to see how many more of these cases there were this year than last. With the severe form of influenza there were very few of these cases, while this year, with the mild form of influenza, they were seeing many more cases of encephalitis lethargica.

Dr. HENRY DWIGHT CHAPIN said he had not seen enough cases of encephalitic lethargica to attempt to make a differentiation between it and tuberculous meningitis.

Dr. MCLEAN said that if the child lived long enough that would decide the diagnosis; if the child lived it did not have tuberculous meningitis.

Dr. CHAPIN said that they could not depend upon the von Pirquet reaction to assist in making the diagnosis, because in tuberculous meningitis one frequently did not get a positive von Pirquet reaction.

Dr. SMITH said he wondered if some of the cases diagnosed tuberculous meningitis in the past might not have been this disease.

Dr. OSCAR M. SCHLOSS said he did not know a definite way of differentiating encephalitis from tuberculous meningitis in the early stages, but that the disease was more chronic than tuberculous meningitis. The cases all ran a long course and often showed some form of paralysis or paresis. Two out of three showed some paresis on one side of the face, not enough to be called a paralysis. The feature that was striking was that they slept all the time; and they went on that way for weeks and months, which was not true of tuberculous meningitis. The spinal fluid changes might be almost the same except that the count was apt to be lower in encephalitis. In some cases, however, there was no increase in the cell count at all.

Dr. BARTLEY said that in the cases of encephalitis lethargica that he had seen there was not the irregularity in respiration and pulse that one saw in tuberculous meningitis, and there were not the pressure symptoms seen in tuberculous meningitis. The cases of encephalitis lethargica went along without change in about the same way, while tuberculous meningitis progressed from day to day. Perhaps it was not always so, but in the cases coming under his observation there were no symptoms of intracranial pressure and no strabismus such as was seen sooner or later in tuberculous meningitis. Paresis might be present in both conditions, so it seemed to him that the significant thing was the pressure symptoms. In tuberculous meningitis the time from the onset of symptoms until death was on an average fourteen days.

Dr. SMITH said it seemed to him that the great difference betwen encephalitis lethargica and tuberculous meningitis was the failure of the former to progress. If one watched a case for three days and there was no change in the condition of the patient, the condition was more likely to be encephalitis lethargica than tuberculous meningitis. A coma lasting ten days was very long in a case of tuberculous meningitis. Dr. Smith stated that he had had seven cases of encephalitis lethargica and they all had catatonia; that feature had been very interesting and striking.

Tuberculous Arthritis.—Dr. FRANK J. BEVAN presented this case, a female child 13 months old, brought to the Babies' Hospital because of swelling of the knee. The swelling was first noticed six weeks before, and had been increasing. During one week before coming under observation the child had had a discharge from the left ear. The family history was interesting in that there were no miscarriages and no exposure to tuberculosis. The feeding history was normal. The child had never been sick before. Six months ago the child began to walk, but gradually became less inclined to try to walk, and after about three weeks would make no attempt to walk. The swelling of the knee had increased and when the knee was handled the child cried out. She had never had night sweats, and had had no vaginal discharge. One week ago the ear broke. This was not preceded by fever. The dis-

charge was very foul. When first seen in the outpatient department of the hospital she gave a positive von Pirquet reaction. The physician who saw the case one week before made a diagnosis of scurvy, and had given the child orange juice. The tonsils and cervical lymph nodes were enlarged. One could barely feel the spleen; the liver was not enlarged; the lungs, heart and abdomen were negative. The left knee was enlarged and the left hip, though not enlarged, was rather tender. There was a typical chronic dactylitis. The case was interesting because the baby was only thirteen months old and showed a typical tuberculous arthritis. They had not yet worked out the bacteriology of the discharge from the ear.

Dr. SCHLOSS said that tuberculous otitis media was not uncommon. He had seen three children under three months of age with tuberculous otitis media in whom a radical mastoid operation was done. Two of these had recovered and were perfectly well; he did not know about the third.

Dr. SMITH stated that he had seen three cases of tuberculous otitis media in one ward in a maternity hospital, and all had developed within three months. They were all submitted to radical mastoid operations.

Myositis Ossificans.—Dr. MINER C. HILL presented this patient, a boy about 12 years of age. He had been nursed for nine months, had had measles, whooping cough, and mumps, and at 2½ years of age swelling on the right side of the neck, which had persisted and become progressively harder. Following this the muscles of the back began to show areas of ossification, and also those of the arms and legs, until at the present time the boy presented many deformities, and presented a striking example of the condition known as myositis ossificans.

Dr. GAYLORD C. GRAVES said that this boy had come to his office about five years ago, having been referred by another physician. At that time no such complete changes were observed as were shown at the present time. There was, however, a very noticeable lesion extending along the posterior surface of the right chest, which resembled periosteitis of the ribs, and although the examiner was not familiar at that time with "myositis ossificans," mention by the boy's mother that a doctor at Bellevue had told her the boy's muscles were turning to bone recalled the term to mind, and led to correct diagnosis. The boy later came to Roosevelt Dispensary, where his history was looked up, and it was found that at Bellevue Hospital a study of the tissue pathologically and also an investigation of the patient's calcium metabolism had been made. *X*-ray pictures taken at Roosevelt Hospital, if compared with those taken at present, would show the progressive course of the disease. The case thus had a very long history, and was interesting because there were on record only 100 to 125 such cases, and also because it emphasized that when one saw this condition a second time he might be observing the same case he had seen before.

Massive Congenital Diaphragmatic Hernia with Dextrocardia.—Dr. H. W. MAYES reported this case, and presented the specimen. The infant, he said, was apparently normal at the time of birth, April 20, 1919. A short time after birth the child became blue, and remained so until the time of death, which resulted apparently from pulmonary edema seven hours after birth. The child was considered a blue baby, but no murmur was detected over the precordium. On opening the chest and abdomen, the left thoracic cavity was found to be filled with the stomach, spleen, pancreas, one-half of the left kidney, part of the duodenum, ileum, and the greater part of the colon. These organs were free in the pleural cavity, with the exception of the kidney. A very small rudimentary left lung, showing division into two lobes, was found in the upper part of the thorax. The heart was completely on the right side. Between the auricles was a small patent foramen ovale. The pulmonary artery was almost as large as the aorta and, lying almost in front of it, was almost continuous with the ductus arteriosus, which was also patent. The right lung was made up of three lobes, and had a large depression filled by the heart. The thymus was normal. The abdominal cavity contained a large liver, which extended down to the brim of the pelvis, a right kidney normal in size and position, one-half of the left kidney, and the sigmoid, which extended in a straight line from the rectum to the opening of the diaphragm. The right side of the diaphragm was normal. The left side showed good muscular tissue, normal attachments anteriorly and laterally, but no attachment on the posterior chest. This left an opening 2 x 5 cm. in size, through which passed the cardiac end of the stomach, a loop of the duodenum, the colon, and the left kidney, making a false diaphragmatic hernia. The kidney was retroperitoneal and formed the posterior boundary of the opening. Dr. Mayes expressed the opinion that the hernia was undoubtedly formed during the early life of the fetus, or they would not have the rudimentary lung on the left side. The dextrocardia was secondary to the hernia. The patent foramen ovale and the ductus arteriosus were due to the fact that the heart was out of its normal position. Dr. Mayes said diaphragmatic hernia was rather common, and true diaphragmatic hernias were more frequent than the false. They occurred more frequently on the left side because the liver was on the right side. Most of the patients died before the correct diagnosis was made. Judging from the cases reported in the literature dextrocardia must have some influence in causing the patency of the foramen ovale and the ductus arteriosus.

A Case of Bacteriemia Treated by Blood Transfusion.—Dr. JESSE F. SAMMIS reported this case. He stated that the patient was an only child, 2½ years old, normally delivered at full term. There was not family history of tuberculosis, the mother and father being well. The mother had had no miscarriages. Up to the time of her present illness the patient had been under the writer's observation at the milk station of Vanderbilt Clinic. The personal history of the child was negative, except for the fact that she had had influenza one year ago, from which she promptly recovered. One week before admission she was said to be feverish and five days before admission compained of pain in the ear. Examination at that time disclosed an acute otitis media of the left each, which was incised and purulent material obtained. Examination at that time showed a well-nourished baby girl who was acutely ill, the left ear discharging, the right ear congested; there was an acute nasopharyngitis; the tonsils were enlarged, swollen, red, and showed many yellow spots; the tonsillar glands were enlarged. The heart was normal. The lungs showed scattered râles. The abdomen was negative. The spleen was not felt. The temperature ranged from 101° to 104° Fahr., until the day of admission to the hospital, at which time it was practically the same as that previously recorded. The child appeared very ill. Cultures from the throat showed the *Streptococcus hemolyticus*. Blood cultures showed many colonies of the same organism. The urine showed albumin and hyaline and granular casts. The blood count showed 23,000 leucocytes and 76 to 90 per cent. polymorphonuclears. Two days later the spleen became palpable, and there were many petechial spots around the ankles and on the abdomen. The child's general condition was considerably worse, the temperature ranging as high as 106° Fahr., with wide intermissions. The child had a general convulsion. A day later the right elbow became red and swollen, and was subsequently incised and pus obtained, which also showed the *Streptococcus hemolyticus*. At this time, the tenth day of her illness, the child was given 150 c.c. of the mother's blood by the citrate method. On the third day she was given 300 c.c., on the twentieth day 125 c.c., and again on the thirty-second day, the mother being the donor each time. Blood cultures taken on the thirteenth day showed only five colonies after forty-eight hours, 2 c.c. of blood being used. Ten days later the same number of colonies were found, and on the thirty-second day three colonies were found; the blood culture became negative for the first time on the forty-eighth day. A vaccine made from the child's organisms was given to the mother, the donor, at intervals of two days for four doses, the number given being 500,000,000 at each dose. On February 3 the agglutinin of the mother's serum against the streptococci isolated from the patient's blood failed to show any clumping in any dilution from 1 to 5 to 1 to 100. In addition to the usual treatment for discharging ears, the throat was sprayed with a

polyvalent streptococcus serum twice a day, and the child placed on a high caloric diet. After the transfusion the child had a reactionary chill, and was invariably listless and very thirsty, and within two hours the temperature usually reached a higher level than just before the transfusion, but gradually declined to a lower level within twelve hours. The temperature reached normal on January 31, and had not been above 100° since then. The pus elbow had completely healed, although there was a slight loss of function. The ears were not discharging, and the appearance of the drum was normal. The tonsils, while still large, looked otherwise normal except for rather large crypts. The child's appetite was excellent, and she had gained two pounds in the last ten days. Her spleen was just palpable, but much smaller than it previously had been. There was slight abdominal distention and constipation, but otherwise the child was normal. Dr. Sammis said that they felt that the repeated transfusions, four in number, were the determining factor in her recovery. When the temperature in the early part of her illness was running very high, and the child losing ground, the advisability of removing the tonsils, the undoubted original focus, was discussed, and it was their intention to remove them if the condition continued to grow more severe, but inasmuch as the child showed slight continuous improvement following the transfusions, this was not done. The number of colonies in the first culture were so numerous that they could not be counted, the second blood culture taken after one transfusion and previous to giving any vaccine to the donor showed a remarkable reduction in the number of colonies, only five colonies to 100 c.c. of blood. The improvement was as marked following the first two transfusions as following the latter two which were given after the doner had been given the vaccines. Inasmuch as the mother's serum did not agglutinate the child's organisms he believed the actual blood was the factor rather than any immunity conveyed in the mother's blood.

Congenital Diaphragmatic Hernia.—Dr. HENRY R. MULLER reported this case, which came under observation at the New York Nursery and Child's Hospital. He stated that the child was a white male, eight months old, who weighed, on admission to the hospital, 11 pounds 6 ounces. The child's weight at birth was 7½ pounds. Vomiting, described as projectile, and taking place immediately after the ingestion of food, had occurred since birth. At the age of six months, and while still on breast feedings, he improved somewhat, and gained 3 pounds 2 ounces in weight; that is, he increased in weight from 11 pounds 3 ounces to 14 pounds 5 ounces. Three weeks before admission to the hospital, at about the age of seven months, he began to vomit all his feedings, even water. Up to this time he had been entirely breast fed, but he was now put on mixed feedings, consisting of three breast and four bottle feedings a day, with irregular additions of zwieback. For a day or two his vomiting stopped, but it recurred, and his condition since then had grown gradually worse. For the past four days the child had been drowsy, and lost during that time 3 pounds 5 ounces in weight. There had been no convulsions, but the child had been coughing and sneezing, and this was followed by vomiting. Physical examination showed a fairly well developed but undernourished child. His eyes were sunken and he appeared acutely ill. His respirations were deep and sighing, and he was semicomatose. The lips were dry and cracked, the tongue coated and the mucous membranes of the mouth dry. There was no evidence of cerebral irritation. Examination of the heart showed the beat in the fourth interspace in the left middle line. The abdomen was scaphoid and symmetrical. The skin wrinkled and inelastic. No tumor mass was palpable, nor were peristaltic waves observed. The liver and spleen were not felt, and there was no fullness in the epigastrium. In the admitting room the child was given three ounces of water, which was taken greedily, but vomited at once with a great gush. The entire mass of water seemed to reach the mouth at one time; the vomiting was not projectile. In the ward the same type of vomiting was observed on attempting to feed the child milk. He could retain only two ounces of albumen water every hour. When an attempt was made to increase the quantity vomiting recurred at once. Intraperitoneal saline injections in large amounts were administered, and glucose solution was given intravenously. The blood examination showed 13,000 leucocytes, of which 52 per cent. were polynuclears. Examination of the spinal fluid and the von Pirquet test were negative. A slight trace of albumin and marked traces of acetone and diacetic acid were present in the urine. On admission the temperature of the child was 99° Fahr. The child died of coma forty-eight hours after admission; the temperature just before death reaching 106° Fahr. Briefly, what was found at autopsy was a diaphragmatic hernial sac, 5 cm. in diameter, situated in the thorax posteriorly, and to the right of the heart. The outer surface was covered with a layer of parietal pleura, and the inner surface was lined with peritoneum. The neck of the sac, corresponding in position with the normal esophageal opening of the diaphragm was circular and 2 cm. in diameter. The muscular layer of the diaphragm could be distinguished up to the neck of the sac, and ended there abruptly. There were no muscle fibers in the wall of the sac, but only connective tissue. This hernial sac contained the entire stomach, doubled up and collapsed, and the omentum. There were no adhesions present. The esophagus, markedly dilated, had its new covering in the upper left-hand corner of the sac, where it emptied into the stomach. The condition then was that of a true congenital diaphragmatic hernia through the esophageal opening. Such hernias were generally considered to be formed late in embryonic development, after the closure of the transverse septum.

Dr. O. M. SCHLOSS said that this case was particularly interesting clinically. The child was seen on account of persistent vomiting, which was the prominent symptom. During the comparatively short period that the child was receiving solid food it gained 3½ pounds. The diagnosis of pyloric stenosis had been considered but was eliminated. As frequently happened in this condition, the diagnosis was not made. The case furnished a strong argument for the use of the fluoroscope in all vomiting babies.

Stated Meeting, Held March 11, 1920.

DR. CHARLES HENDEE SMITH IN THE CHAIR.

Advantages of Boarding-out Care Over Institutional Care.—Dr. MINER C. HILL presented this paper. (See MEDICAL RECORD, page 692.)

Problems of Boarding-out With an Attempted Solution.—Dr. HENRY DWIGHT CHAPIN read this paper. (See MEDICAL RECORD, page 677.)

Boarding-out Department of the New York Nursery and Child's Hospital—Miss EDITH A. HOOPER read this paper by invitation. She said that the New York Nursery and Child's Hospital was one of the first institutions in New York to place children for care in private families, having adopted this method of caring for its dependent children in 1902. The hospital was used only for its proper function, namely, the care of children acutely ill. The aim of the hospital was to replace the motherly care and normal family life of which it was a calamity for the child to be deprived, and to provide such preliminary hospital care as might be necessary for acute illness, correction of physical defects, or indication of a course of treatment to be administered in the home. From 800 to 1,000 of the dependent children of the city of New York passed under the care of the hospital each year. The age of the children ranged from a few days to seven years, the majority at present being between three and four years old. The boarding-out department had therefore the threefold problem of providing wet nurses for the youngest infants, intelligent and experienced foster mothers for the bottle babies, and the comparatively easy task of finding homes for children of from two to seven years of age. The nursing staff of the boarding-out department consisted of a supervisor and five graduate nurses. During the summer months an additional nurse was employed. There were also two Italian interpreters. One of the attending physicians was the consulting director of the department, and to him were referred all the major questions concerning the health of the children in the

boarding homes. These homes were situated within a radius of thirty miles from New York. Of the 220 homes at present in use, only sixty-three were in Manhattan or Brooklyn, while 157 were in the country and suburban districts. The homes were those of respectable middle class families. Many of them were well to do, while none were selected whose object in boarding children was of a commercial nature. The preliminary requirement for a home was a permit from the local board of health. This having been obtained the prospective home was investigated by the nurse in whose district it was located, and a detailed report of the conditions was written. The impression produced by the woman herself was noted, her apparent attitude toward children, her intelligence and experience with babies, her husband's employment and salary, and the number and ages of the members of her family. The names of three references were required, from whom opinions were obtained regarding the character and sobriety of husband and wife, their standing in the community, their financial condition, church affiliation, and desirability as foster parents. The youngest babies were placed with Italian wet nurses whenever possible. These wet nurses were required to present a certificate of health from the physician who attended them during confinement, and a Wassermann test was made and a wet-nursiug permit issued for them by the board of health. It was not usually possible to demand as high a standard in wet nurse homes as was required in others. The nurse and her family must be healthy, the baby must have its own crib, must be bathed and nursed regularly, and must have plenty of fresh air. Wet nurse babies were visited twice a week by the nurse, or oftener if necessary. Homes for bottle babies were hard to secure, most of the women preferring runabouts. Bottle babies were visited once a week; for any radical change in feeding the baby was brought to the hospital for the physician's orders. Nursing and bottle babies under fifteen pounds were weighed each week in the homes on hand scales carried by the nurse. The average gain was a pound a month, although some of the babies gained a pound and a half. The older children were visited every three weeks unless more frequent visits were needed. Any matter of interest was reported. The child's teeth were watched, and the necessary dental care was obtained either from clinics or from a private dentist. Advice was given concerning small ailments, or the foster mother was directed to bring the child to the hospital clinic for medical advice. In case of graver illness of children in boarding houses one of two courses was pursued. The child might be admitted to the hospital, or it might be cared for in the home under the direction of a private physician, and with the supervision of the visiting nurse. Minor illnesses and cases of contagion were usually cared for in the boarding homes. There had been during a period of several years only one death and one complication from any case of contagion cared for in our boarding homes, which contrasted sharply with the death rate of their cases when sent to contagion hospitals. The number of children under supervision during the years 1918 and 1919 was 1,256, the number dying 39, giving a mortality of 3.1 per cent. The hospital provided a plentiful supply of attractive clothes for its children, making every effort to avoid that which was institutional, and found this an aid in securing and retaining homes of the better class. By this method the child received a happiness and personal development which would not be possible in even the best institutions. and was able to take his place in the world without the handicap of an unnatural childhood.

Dr. Smith said he hoped he would be pardoned for speaking at this point in the meeting, but there was one aspect of this problem which had been touched upon only lightly and which he wished to bring out before the discussion rather than after it. This was a matter of temporary care for infants in emergencies. Dr. Smith said he did not wish to uphold the institutional care of infants as opposed to boarding out in the least degree, but he thought there was a place for small, well-conducted temporary shelters to meet sudden emergencies or for cases where the care need to be only very short. The Manhattanville Day Nursery had been conducting an experiment in this kind of care for the last two years. The managers of this institution had believed for a long time that their was an urgent need for emergency care, consequently when their new building was erected, one ward was set aside for day and night care. This ward was especially equipped with glass partitions, forming small cubicles for each bed. This separation of the patients, with careful examination and history of exposure on admission, had seemed to control the contagious disease problem. Whooping cough, chickenpox, scarlet fever, diphtheria, and influenza had all been admitted during the incubation period, however, but in no instance, up to the present time, had there been any development of secondary cases. Day and night care required more highly skilled attendance than the ordinary day nursery staff. It had been found necessary to have a trained nurse for superintendent and a trained nurse in charge of the night baby room, with two or three untrained assistants. These cases required more frequent visits by an attending physician also. In spite of the cost of the extra equipment and the extra cost of maintenance for this work the Manhattanville Day Nursery felt that it was very much worth while. As a matter of fact, the receipts for the care of these twelve to fourteen babies were nearly one and two-thirds' times the receipts for the day care of approximately fifty-five children. While it was not possible to say that the night babies actually paid for their keep, they very much more nearly did so than the nursery children who were supposed to be the main business of the nursery. Babies were taken whose mothers had suddenly become acutely ill or died. In such cases boarding out was very difficult and temporary shelter must be found until the family had a chance to look around and readjust itself. During the mother's absence for confinement or surgical operation, the temporary shelter also was of value and the institutional care was not prolonged long enough to do the child any great harm. It seemed as if there was an obligation imposed upon the day nurseries to take up this work more generally. At present there were thirty-one children on the waiting list for "emergency" care at the Manhattanville Day Nursery, so the need was obvious. The hospitals were not equipped, with few exceptions, to admit well babies. The day nurseries would seem to be the only agencies to properly step in. Great pressure was being brought upon them to take up this work more generally.

Hon. John Kingsbury, Ex-Commissioner of Charities of New York City and at present head of the War Relief in Serbia, expressed sorrow that New York City had not grasped its opportunity to get behind a work like that done at Speedwell, or such work as was being don at the Manhattanville Day Nursery which was a step towards Speedwell. Years ago Dr. Chapin had shown by his work at Speedwell what could be accomplished by boarding children in homes, yet the city went on putting more and more money into institutions. If that money were put into skilled nursing case for children in homes thousands instead of hundreds of children could be saved to-day. He believed, however, that this method of caring for dependent children in homes was coming and that New York would soon wake up to its opportunity. Physicians knew the number of children in institutions and that the death rate was cruelly and murderously high. If one wanted to get some idea of what the death rate had been he need only read the records of Randall's Island before it was used as an institution for the feeble-minded. Forty or fifty years ago Randall's Island was a morgue for little babies, the death rate being 100 per cent. That was decreased when they began to board babies out. After all we had made great progress and should not be discouraged. Mr. Kingsbury then told what was being done for the babies of Serbia. He said that Serbia had lost more in the war and had less to-day than any of our allies. There was a popular illusion that Belgium was the greatest sufferer in the war, but the truth was that Belgium had suffered the least with the exception of the United States in both loss of life and property. Serbia was to-day a country of widowed mothers and children; the babies had mostly died. But Serbia through all her sufferings of a thousand years had still an unconquered soul. Serbia was going to profit by taking the stand that it was better to

die in beauty than to live in shame. But she was not going to die; she was going to live. She had written on her statute books the most progressive child welfare laws. To-day Serbia had elevated the importance of the child to the extent that she had created a special cabinet office and had a national department of health. In this country we had a Bureau of Child Welfare tucked away in one department and a Bureau of Public Health Service in another department. Serbia wanted the experience of America. They were asking for trained nurses and doctors, and were going to ask the experienced men and women of this country for the benefit of their experience. They were going to ask these doctors and nurses to go over and to translate into action the legislation which they had enacted. If this was carried out even to the extent of 50 or 75 per cent. it would place them in the position of leaders in child welfare and public health work. Serbia was translating into action what we had considered as ideal. As he had said on previous occasions the home with the mother in it was a better place for children than the best managed institution in the land, and he was glad to hear that there was a movement toward having these plans carried out. They were going to carry out similar plans on the other side of the water.

Dr. PHILIP VAN INGEN said he did not think many of us realized what Dr. Chapin had been doing for the last eighteen years. The Speedwell Society which, at any rate until within the past few years, was Dr. Chapin, had done a splendid work. Mr. Kingsbury had spoken of the statistics of Randall's Island forty or fifty years ago and stated that we had made great progress. It was true we had. Seven years ago, Dr. Van Ingen said, he had had occasion to look into the mortality of the children under two years of age in New York State. During the period studied there were 28,210 children cared for by eleven institutions and the death rate for children under two years of age was 422 per thousand, or almost one-half. In New York City at the same time in one institution the mortality rate for children under one year of age was 516 per thousand. That was what had been done up to seven years ago. One great trouble was that it required too much red tape to get the children out of the institutions. The child was usually dead before anything could be done, but at last someone was trying to meet the emergency. Austria-Hungary was not a popular country to talk about, but in 1903 they passed a law that every child under fifteen years of age was entitled to care, clothing, food, education, and a home. If a child did not have parents who could give these things it was the job of the state to see that he got them. In 1910 this system was developed to such an extent that no matter what the cause any child brought to one of the seventeen state asylums was admitted. If it was found that the parents could support the child they were compelled to do so and to pay a penalty; if the parents could not support the child the state took care of him. The child was kept in an institution long enough to see that it was physically fit, or not acutely ill, and then placed in one of the colonies of which there were 374 in the country, and in these colonies they had a mortality of 200 per thousand. At a little later date in our State we had a mortality of 422, and in one institution 517 per thousand. Many of these children under state care in Hungary were illegitimate and as was well known the death rate among this class of children was high, so that they had really accomplished something. The one thing that stood in the way of our work in this country was that we did not know what other people were doing. We started a great many excellent things and after they were fairly started we found that other countries had been doing these same things for many years. That applied to child welfare work, maternity centers, etc. As an example of the poor management that had been noted Dr. Van Ingen recalled an instance that occurred when Mr. Kingsbury was commissioner of charities and of which Mr. Kingsbury had told. A woman with six dependent children went to the Department of Charities to get relief. They said they would give her some help so they took away four of her children and gave her four children from an institution to board.

Miss ROGERS of the Henry Street Settlement stated that the Henry Street Settlement had always emphasized home care for children, and, while the nursing service exemplified the care of sick children rather than of dependent children, they would be most enthusiastic over one of Dr. Chapin's institutions in their neighborhood. The visiting nurse had long stood for the educational and social factor in the community, which was a very large factor. The training schools for nurses had contributed so far much more towards enlarging the opportunities for nursing by giving a worthwhile service in pediatrics. They felt that in any nursing service the nurse must have a large understanding of children and in field work she might develop that understanding in a complete way. The nurse had to do much as the social worker did in entering a home; she had to adapt the necessary care of the child to the environment in which she found the child and this was considerable of a problem. One encountered many difficulties, for there were many natural guardians who did not recognize their responsibilities. In meeting and solving these problems much could be done by the visiting doctor and nurse. They could insist upon certain requirements. The Henry street nursing service had shown what could be done in the face of adverse circumstances in the care of the sick child. Pneumonia, gastrointestinal conditions, and many communicable diseases were successfully cared for in the home, as well as much maternity work. Statistics showed that about 90 per cent. of all sickness was cared for in the home. There were 4,683 maternity cases cared for by the Henry Street Settlement with 4,348 living births where the mothers were under prenatal care and supervision; the infant death rate per thousand was 9.8 for nearly 5,000 cases. Among a thousand in whom the care and supervision was only post-natal the mortality was 14.2 per cent., the city death rate for infants under one month of age being 37 per thousand. The miscarriages and abortions under prenatal care were 6.8 per thousand; the number where there was no prenatal care was 35.7 per thousand, and the number of still births under prenatal care only 21 per thousand. Where there was post-natal care only the number of deaths per one thousand births was 34.5. Their figures for feeding cases were much more difficult to give because of the many agencies engaged in this work, but those for pneumonia were more interesting. The number of pneumonia cases cared for in 1916 was almost 4,000 with a mortality of 8.6 per cent. Out of this number 1,564 were Italians with a mortality of 181 or 11.6 per cent.; 1,221 were Hebrew with a motality of 38 or 3.1 per cent., giving an interesting contrast as regards nationalities. They found a marked difference as regarded nationality in studying the feeding cases. One found many cases of rachitis if he went into the Italian districts. In 1916 and 1917 the average death rate from pneumonia in the age group under five years was 8 per cent., while during the influenza epidemic it was 16 per cent., twice the usual rate for pneumonia. The visiting nurse needed to do much more than merely observe the sick when she visited a home. She had to recognize the family group and the social responsibilities. Frequently social conditions underlying the illness and the social condition was a much bigger problem than the actual illness. Frequently these conditions had to be considered in cooperation with affiliated agencies. The dependent child or the one that needed supervisory care they met with every day and they wished they might have larger and better facilities to-day in meeting that need.

Miss THEIS of the State Charities Aid Association told of the work of this organization in placing children in permanent homes. She stated that their experience bore out what Dr. Chapin, Dr. Hill, and Miss Hooper had said as to the better development of children in the home. In regard to the death rate in homes, their children were mostly in free homes and they did not have a death in 1916. In 1918 and 1919 there were six deaths, four from influenza, one from pneumonia, and one due to accident. Various phases of the boarding out problem had been considered but no one had spoken of the child's own viewpoint. The speaker said she had personal oversight of 2,000 chil-

dren placed in temporary boarding homes in preparation for permanent homes. Almost without exception the children wished to remain in the homes. She had asked the staffs of the institutions from which these children were sent how many wished to go back into an institution and they had known of only six children who wished to return. It was most convincing that these children did not want to go back into an institution even though the homes in which they were living were by no means ideal. The Nursery and Child's Hospital furnished them with the largest number of children. One of the advantages of the boarding out system was its elasticity, inasmuch as the size of the organization could be increased or decreased as the need required.

Miss ARNOLD of the Babies' Welfare Association said that speaking for all the social workers she could say that they were looking for the day when the Speedwell idea would be generally adopted. The agencies doing that work had long waiting lists of children who should receive that care. There was also a demand among parents for boarding homes for children. They had had 1990 parents seeking homes for children for whom they wished to pay. There were 2,000 homes licensed by the Board of Health. A duplicate list of these homes was given to the Babies' Welfare Association so that they could know where they could find homes that would provide care for their children. Through the Bureau of Child Hygiene they also received lists of homes. In boarding out children they demanded of the woman who took the child that she should take it to a milk station. They then telephoned to the milk station and had them see that the baby was duly enrolled. There was at present more of a demand for foster homes than there were homes, especially for young babies, and they had offered special inducements in order to find homes for a limited number of babies, and they could not find homes at even $10 a week. There was a wonderful field for this kind of work. Where mothers had died the fathers were very anxious that their children should have home care. The Babies' Welfare Association had 156 homes about which it had special data for parents. She thought that Mr. Kingsbury would be interested to know that a large majority of their 1990 babies came from the Department of Charities.

Dr. SIDNEY V. HAAS said he wished to say a word in favor of institutions, though of course everyone familiar with this question knew that even in a poor home a baby was better off than in the average or perhaps in any institution, and no one deserved greater credit for trying to force this fact on the public than Dr. Chapin. But after eighteen years of effort the results showed housing for only a small group of children. All who had spoken had mentioned only a few thousand boarding homes. Mr. Kingsbury, several years ago, said there were several hundred thousand children requiring such homes. What were they going to do with the children in the interval until a boarding house system was built up and sufficient homes secured? There was at least one institution in the city the statistics of which were quite different from those they had heard this evening. This was the Home for Hebrew Infants; there they had had a death rate between 1915 and 1919 of from 3 to 7 per cent. They had the death rate of 7 per cent. in 1917, when they had an epidemic of measles. The year of the influenza epidemic they had a 6 per cent. death rate. In normal years the death rate was about 3 per cent., and they housed about 400 children under five years of age. These children did not look white and marantic. As a matter of fact, they compared favorably with children in private homes. They often received children in deplorable condition and after having them for a time showed just such results as Dr. Chapin had shown they were getting at Speedwell. Some of these cases were received from boarding houses. This did not mean that in boarding the children out they were not doing good work: it only showed the difficulties of the problem and what a great field under present conditions would have to be covered. If it could be undertaken by the Government it might be made possible. It might also be of interest to know the cost of caring for these children in the Hebrew Orphan Asylum. The cost of caring for the infants was $7.30 per capita per week, about what Dr. Chapin's babies cost. In 1918 the cost was $8.12 per week, which was less than Dr. Chapin's estimate for that year. It might also be of interest to know that since May, 1916, they had been using the Shick test except in a small group which was used as a control—no case of diphtheria occurred except in this group. Diphtheria was practically eliminated from this institution. While they were attempting to obtain proper homes and to build up a practical Speedwell system, institutions could be improved and by the adoption of the cubicle system the children could be kept free from contagious diseases. Many of the children at the Home for Hebrew Infants were the ruddiest, finest youngsters, so he thought that, while they were waiting for Dr. Chapin's system to develop, they should not lose sight of the many things that could be done by improving institutions.

Dr. SMITH said that Dr. Haas did not mean that the institution was superior to the home, but that it should be improved and helped until the children could be boarded out.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Miscellany.

Death of Professor Lepine.—Raphael Lepine was born at Lyon, in 1840, was interne during 1860-4 in the Lyon hospitals and then, still unsatisfied, continued his internate in the Paris hospitals, Clemenceau being a fellow-interne. Among his teachers he learned most from Charcot, who gave him his scientific bent of mind. Unlike most of his colleagues, he went to Germany for study, and between 1867-70 was a pupil of both Virchow and Ludwig. He became on his return prosector for Brown-Séquard until the outbreak of the war, through which he served with credit. This concluded he became Germain See's chief of clinic and a professor agrégé of the faculty of the University of Paris. From this time on he was a figure of prominence in medical Paris, but in 1898 returned to his home town of Lyon as executive of the combined hospitals of that metropolis and president of the Council of Hygiene for the Rhone department. Here he remained until his retirement in 1914. He was an unusual combination of clinician and pure scientist, as shown by his writings. These dealt with the histology of the brain (he discovered the perivascular spaces of the nervous centers); with the anatomy and physiology of the vasomotor nerves, he being the discoverer of certain vasomotor fibers and centers; with clinical neurology, being the first to describe cerebral pseudobulbar paralysis, with internal medicine, as seen in his early work on caseous pneumonia and renal diseases, with therapeutics—he wrote many papers on drug action, etc., etc. His master work is his volume on diabetes, which did not appear until 1909. This was the product of twenty years of research, and he continued this line of activity, his work on blood sugar being actually in press at the present time. Biography has few parallels of this 80-year-old man seeing an important volume through the press. With Charcot and Vulpian he founded the *Revue de Médecine* and with Charcot the *Archives de Médecine Experimentale.*

Death of Nissl. — This distinguished Bavarian histologist, neurologist and psychiatrist, recently deceased, receives a memorial notice in *Hygiea* for December 31, 1919, lxxxi, 24. He was born in 1860, in Bavaria, and was originally intended for the priesthood. He was graduated at Munich in 1884, and won a prize for his work on the pathological changes in the nerve cells of the cortex, when only 24 years of age. His teachers were Gudden and Ganzer. With Golgi and Ramon y Cajal he divides the credit for most of the earlier technical advances in the histology of the cortex. After the death of Gudden he became associated with Alzheimer and combined histological studies with animal experiment. The epoch-making work of the clinician Kraepelin was made possible by the labors of Nissl and Alzheimer and both of the latter associated themselves with Kraepelin's clinic at Heidelberg, which he took over in 1895. Here Nissl remained as associate until 1914, when Kraepelin was called to Munich, whereupon Nissl became chief of the psychiatric clinic at Heidelberg. However, he soon followed Kraepelin to Munich, where he became head of the anatomical department of the clinic. His death occurred in August, 1919.

History of Gynecology and Obstetrics in Strasbourg.—Professor Schickele, who was Fehling's assistant in the German University of Strasbourg when the war broke out, succeeds Fehling as the holder of the chair of obstetrics and gynecology of the new French University. Recently he delivered a lecture on the above subject, which appears in *La Presse Médicale* for January 24, 1920, xxviii, 7. In 1513 was published the pioneer volume on midwifery at the Alsatian capital, Roesslin being the author. This went through many editions and translations. In 1728 was founded the first school for midwives, with Fried as its first professor. In 1737 medical students were already being instructed in obstetrics in the university by means of the mannikin and observation of actual labor. Students were allowed to confine women themselves under supervision. Thirty beds were available for teaching. Strasbourg became famous as the place where both doctors and midwives were trained for obstetrical work. Several extant theses by Fried's pupils have no little practical value. Strasbourg preceded Paris by a full century in the introduction of a complete obstetrical clinic as part of the university course (Fried was never a member of the university faculty). The first actual professor of obstetrics in the whole of France, Flamant by name, was appointed at Strasbourg in 1798. His chair had no connection with the school for midwives. The latter, despite able directors, yielded little by little to the regular obstetrical clinic of the faculty, the material for teaching being diverted to the latter. In 1847 the two schools were consolidated as part of the university for the first time and placed under Professor Stoltz. The latter was a tower of strength in the old French University, and was in the van of all progress. As far back as 1857 Levy, a student, wrote under Stoltz's inspiration his thesis on the infectious nature of puerperal fever. Other students found organisms in the blood of septic women which may have been the vibrios seen later by Pasteur. Stoltz was succeeded by the equally eminent Koeberle, one of the earliest of the aseptic surgeons and gynecologists. After the Franco-German war nearly the entire medical faculty of Strasbourg moved to Nancy. The first incumbent in the new German University was Freund, whose services to gynecology are too recent and well known to require detailed enumeration—he was specially interested in the radical operation for cancer of the uterus. This account terminates with the end of Freund's service in 1901 and the work done by Fehling and his assistants, including the author, is not mentioned.

Bathing Habit Acquired in Montenegrin Town.—When the Americans came to Podgoritza they found that city of 10,000 inhabitants innocent of public bathing facilities. Many native doctors believed that the frequent use of soap and water was harmful, and had succeeded in instilling into the minds of the people a decided fear of bathing. The Red Cross doctors and nurses went on the theory that bathing, like caviar, was an acquired taste, and in order to popularize it they made it a condition precedent to being placed on the free provision list. The taste once acquired under this compulsion, its popularity gradually increased, and the Montenegrins have now learned to like the bath.

JEROME M. LYNCH, M.D., F.A.C.S.

NEW YORK.

ATTENDING SURGEON, ST. BARTHOLOMEW'S HOSPITAL FOR DISEASES OF THE ALIMENTARY CANAL, NEW YORK CITY; NEW JERSEY STATE HOSPITAL AT TRENTON.

(From the Surgical Clinic of the New Jersey State Hospital at Trenton.)

THE fact that there are over four hundred thousand men and women chronically insane in the hospitals of the United States and that in Massachusetts the ratio of insane to the general population is one to two hundred and fifty prompts the question, "What is being done for the insane?" The answer is certainly appalling to one who has made even the most superficial examination of the existing conditions. The ratio of recovery to the admissions is exceedingly low; thus in Massachusetts, for the whole State, it is only 6.9 per cent.,[1] and if the cases designated as "improved" are included the ratio is only 24 per cent. If this is true of so highly developed a State, which has led to a great extent in civic betterment for years, and where therefore the established methods of therapy are undoubtedly at their best, what must be the situation in the rest of the country! Is it in part due to the segregation of the insane in great institutions, invariably located in the most inaccessible regions and as far as possible from medical centers and points of contact with progressive medicine, or to the quiescent acceptance of the old traditional ideas that the insane are stigmatized and that therefore they do not require or are not entitled to the ordinary modern medical attention given to the people at large?

Whatever the cause or causes, there has been undoubtedly an entire lack of cooperation between the progressive medical men and those entrusted with the care of the insane. And even locating expensive psychiatric clinics in connection with prominent medical schools, as for example the Psychopathic Clinic in Boston, has not materially assisted in overcoming this condition. While the study of psychiatry has been stimulated, this lack of cooperation so necessary between the various branches of medicine has militated to prevent the best results.

A great opportunity for synthesizing psychiatry with scientific medicine was lost during the war, when an ideal condition existed in that the psychiatric wards were included in the scheme of the base hospitals, and every facility for the interchange of ideas between the highly coordinated departments was offered. This opportunity was brought about by the very meritorious work of the National Committee of Mental Hygiene, for without their appreciation of the importance which psychiatry would assume in the war even this would have been neglected. But unfortunately the existing facilities were not made use of except to a very small extent, and aside from acquainting the many medical men with the importance of the problems of mental diseases no constructive work resulted.

Nevertheless, while admitting that psychiatry has lagged behind some other branches of medicine, especially surgery, we would call attention to the fact that a good many chapters in internal medicine had to be written before psychiatry could emerge from that obscurity as a science to which it was condemned because of a lack of the proper methods. Only in recent years have modern methods become available. We refer especially to the recognition of the theory of focal infections, largely through clinical pathological laboratory research. While it may be said that this doctrine has not been generally accepted, at the same time it has already furnished an entirely different viewpoint in the etiology of some of the more obscure disease processes and opened up an entirely new field of investigation. This has been especially true in the study of the etiology of the psychoses, as has been shown in previous publication from the New Jersey State Hospital at Trenton.

Indications of Intestinal Infection.—As a result of eradicating focal or chronic infections in the group of patients usually placed in the functional psychoses, we have been able to restore 270 patients out of a total of 410 admitted during the year ending July 1, 1919, and they were discharged during that year. By re-examining the remaining 130, we were able to find local foci which had been overlooked and by January, 1920, this number had been reduced to 100. In other words 75 per cent. of this group, or 310, when the local foci of infection found in the teeth, tonsils, stomach, and cervix were eliminated, were able to be discharged and returned to their respective homes. The remaining 25 per

*Read before the Northwestern Medical Society, New York City, February, 1920.

cent. apparently did not react to the treatment mentioned and remained unimproved.

The object of the investigation, of which this is a preliminary report, was to search further for possible sources of infection, mainly in the lower intestinal tract. This group suggested terminal ileac and colonic trouble because of frequent "bilious attacks" during youth; habitual constipation, sometimes alternating with diarrhea; intermittent attacks of abdominal pain and not infrequently a history given by the mother of intestinal disturbances beginning in early infancy. A thorough physical examination revealed the sallow face, indented tongue, narrow costal angle, and the usual costo-umbilical measurements of a chronic intestinal invalid, frequently hyperontomorphic in type. In addition to these characteristics there was found usually unilateral tenderness and rigidity of at least plus two over the right lower quadrant of the abdomen. In over 90 per cent. of the cases this condition was confined to the right side. Frequently the abdomen was doughy, the abdominal muscles lax and without tone, and in over one-half of the cases examined Coombes' sign of "snow crepitation" over the cecum was present. In these cases there was also found the usual splashing and evidence of cecal dilatation.

In the patients who were capable of cooperating, radiographic studies confirmed the physical findings. The interpretation of the *x*-ray plates was based upon the functional rather than the morphological findings. Cecal and ascending colonic delays of from three to seven days have been the rule. The radiographic studies determined whether the pathological condition was on the right or left side, or, as was occasionally the case, on both sides. The routine use of the barium enema, followed by a twenty-four hour plate to determine the degree of retention, has been found to be most important. It is notable that a very small percentage of cases examined have shown ileosphincteric leakage.

The above described examinations justified an exploratory laparotomy in these cases and the pathological findings justified surgical intervention. As the literature in this field is particularly sparce our first investigations were made upon the most chronic and hopeless patients in the hospital, in which, owing to the known degree of deterioration in the mental field and a corresponding degeneration of the cerebral cortex,[8] no marked curative effects were to be expected. The intestinal surgical pathology, both as to the degree and extent of the lesions revealed in these patients, more than justified our expectations. After studying twelve such chronic consecutive cases, and without a single failure to find a great variety of intestinal lesions, we were convinced that it would be conservative surgery to explore the abdomens in the more recent cases which had not responded to the routine treatment, teeth, tonsils, etc., outlined above.

Therefore, as rapidly as possible all such patients capable of cooperating were *x*-rayed and otherwise studied from the standpoint of the abdominal surgeon. The *x*-ray and surgical technique adopted was the same as that used at the St. Bartholomew's Hospital for Diseases of the Alimentary Canal, New York.

At the completion of the twelfth consecutive case of the more recent type, we were greatly encouraged to find that without a single exception they were just as prolific in furnishing pathology as had been the twelve chronic cases. From our experience with these twenty-four cases we were convinced that all patients who showed any tendency towards chronicity, or who did not improve under the routine treatment directed toward the removal of infection in the teeth, tonsils, stomach and cervix, were cases which should have a thorough investigation of the lower intestinal tract with a view to surgical intervention. These cases must be subjected to the most thorough and minute physical and laboratory examinations, similar to those employed in the best general and special hospitals. And a surprisingly valuable surgical history of abdominal trouble can often be obtained by patient questioning. If not from the patient, relatives can often furnish it. This is of the utmost value and should never be overlooked. Fortunately the State Hospital at Trenton possessed the necessary *x*-ray equipment and laboratory facilities, as well as the necessary operating room and staff, to undertake this investigation.

The results of the preliminary work have been so gratifying that the staff was eager to assume the additional work imposed by the new requirements. The result of examining all new patients from the standpoint of modern medicine has been the transformation of a State Hospital, exercising the usual custodial care, into a modern institution devoted to diagnosis and surgical and medical therapy. As such it is on a par with the best modernly equipped and conducted general hospitals and in addition its surgical clinic has developed along advanced lines in intestinal pathology and bacteriology necessitating pioneer resarch work in these important fields.

This investigation has not been limited to the gross surgical pathology, but has been accompanied by elaborate laboratory researches including both bacteriological and histological studies. Indeed we are convinced that important as are the usual gross and microscopical studies, there is no collaborating department in medicine as important to the progress of intestinal surgery as bacteriology. So close is the affiliation of these two branches of medicine that surgical bacteriology has become to us the most important part of surgical pathology. It teaches what we are dealing with. We need information from the living more than from the dead. (See Fig. 1.)

The finding of various strains of the streptococcus group and colon bacilli in cultures from the enlarged mesenteric glands in the colon region, or in other parts of the intestinal tract, were important in linking up lesions of the colon with the psychoses and the proven presence of these bacteria in the walls of the intestine gave further evidence of the rôle played by infection in producing the toxic phenomena described under many forms of mental disease.

Our work has further demonstrated that we are dealing with an infection of the wall and tissues of the intestinal tract and explains the fact that treatment directed towards the lumen or intestinal cavity has not been effective in clearing up this type of infection. (See Fig. 1.) The futility of the thera-

peutic efforts to cure the chronic intestinal invalid by cleaning out the intestinal tract or by changing the intestinal flora is demonstrated. For the bacteria have entered the tissues and they cannot as yet be successsfully eradicated without radical

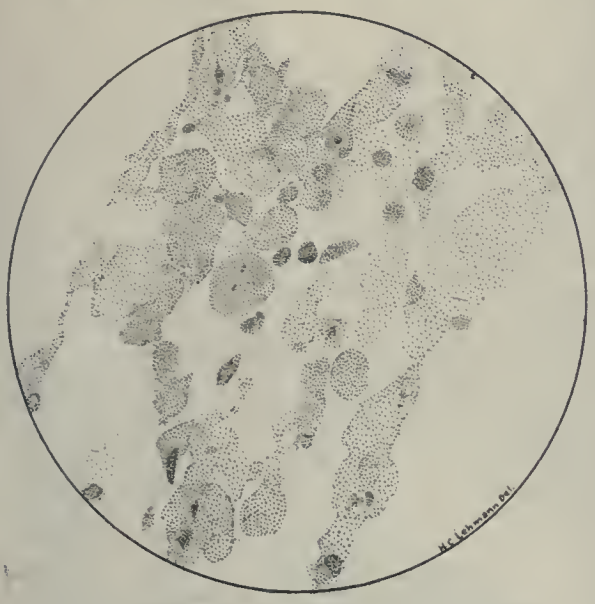

Fig. 1.—Bacteria in the tissue of the stomach wall.

surgical measures to remove this infected area. When the infected area of intestine is too extenive for surgical removal then we have had to depend upon serum or vaccine therapy. But without the knowledge gained from the exploratory laparotomy in these cases we should have been at a loss to formulate any method of procedure based upon the now known pathology. In several cases (notably I. S.), it could been seen by actual observation at a secondary operation nearly three months later that the antistreptoccic serum had had a most definite effect upon the mesenteric glands which were found to be enlarged at the first operation, and at that time gave positive cultures of streptococcus and *B. coli.* When they were examined at the secondary operation the glands had become much smaller in size, showed evidence of recessive changes, and were sterile when cultured. Judging from the extent of these enlarged glands throughout the whole intestinal tract, we would be justified in concluding that here the infection involved both large and small bowel. In such cases, and we have seen many, it would be futile to remove the right colon as it was only a part of the involvement. Its resection would have had very little if any effect upon the infection of the upper tract. When the colon is very markedly involved and the upper tract also we are justified on the theory of attrition in removing the right colon and then adopting measures which will improve the other infected areas. In the case cited above the improvement in the patient was synchronous with the disappearance of the infection and she was able to return home where she has been for the last eight months, and this after a residence, prior to operation, of a year in the hospital.

Surgical Pathology.—From the variety of lesions found in our series (Figs. 1-5), it has very definitely demonstrated that no one surgical procedure is adequate to cope with the situation. That is to say that the method to be adopted in an individual case must be determined frequently after the abdomen is opened, as each case presents its own problem. Therefore it is impossible to recommend any definite procedure as the operation of choice. As in general abdominal surgical practice, it is here equally impossible to determine the exact nature of the lesion from the preoperative studies, and a thorough biopsy with a careful examination of every organ in the abdomen is most essential. Preliminary studies can be made sufficiently accurately to determine that a given case is surgical and that another is not. But today no one can go much further than this. Every abdominal operation therefore is exploratory as regards the character of the lesions to be found, but positive as regards the presence of pathology which today can be remedied or helped by surgery alone.

We recognize the fact that a great deal of surgery has been done among the insane, but the reason that it has not been productive of results has been that its aim was in the wrong direction. Five years ago we published a paper citing two cases of insanity due to absorption of bacteria and their products from diseased cecum and colon, concluding as follows: "One characteristic result of

Fig. 2.—Case of paranoia with extensive pathological changes in the interior of the cecum. There is ileocecal sphincteric insufficiency, as shown in the enlarged view of the sphincter, below the main figure.

this toxemia is mental depression, which may even go so far as to result in mania."[4] Thus Robert T. Morris[5] in an article published in August, 1918, pays his respects to the Freudian conception of mental disease, and discusses in a very logical

manner the relation of physical conditions to the psychoses, and shows a surprising familiarity with the problem of the treatment of the psychoses. He says, "Surgery aimed directly at the cure of the psychoses and the psychoneuroses will be a failure

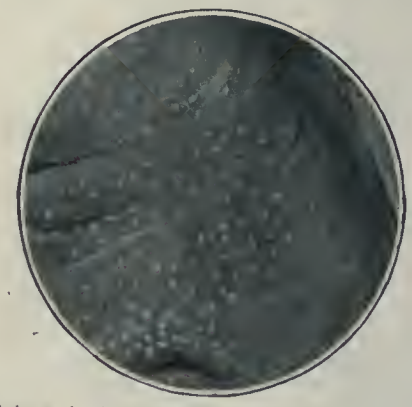

Fig. 3.—Enlarged view of a portion of Fig. 2, showing the area of minute ulceration.

because so many factors are involved, but surgery which removes peripheral irritations and focal infections among the insane and among the psychoneurotics will have many spectacular recoveries from the insanities to its credit." One can but admire the vision of this surgeon who persisted in spite of the prevailing opinion of the psychiatrists.

Surgery directed towards the correction of "abnormal position" and the "relief of pressure" is absolutely futile. For example the raising of a so-called fishhook, ptosed stomach by slinging it in the omentum or otherwise, or the replacement of displaced uterus is destined to fail because its premises are altogether wrong. Such work is done without recognizing that on one hand the position of the organ is normal to the hyperontomorphic type and is harmless unless infected, and on the other hand that a retrodisplaced uterus in a flat-backed woman is its normal position and is equally harmless unless infected from the cervix.[7, 8] We are convinced therefore that the only surgical procedures which are justified in the therapy of the psychoses are those directed strictly against infection. Obviously if the bowel wall and its mesentery are infected, except this be localized in a relatively small segment in the terminal portion of the alimentary canal or in the stomach, surgical procedures at present are futile because of the impossibility of resecting the oral portion of the small bowel. We are of the opinion that if the mesentery of the jejunum is involved, and this is the only discoverable pathology, vaccines or sera are the only hope for the patient. This conclusion was reached after we had irrigated the small bowel from end to end over periods of many weeks and with Dakin's and other solutions. Moreover this supports the statement already made that the treatment of the lumen of the tube is of little avail because it does not reach the infection of the wall. It also gives support to the belief that certain areas of minute ulceration (see Fig. 3), found by careful examination of the mucosa of excised segments may be the portals of entry of bacteria and their products from the inner surface of the body to the body cavity proper. Of course, infection may occur without such portals of entry.

We wish to emphasize the fact that in all our cases laparotomy has not been undertaken until the removal of all other discoverable foci, especially those in the teeth, tonsils, cervix, stomach, and duodenum. We would further emphasize the fact that these abdominal procedures are based upon very definite researches in the surgical and bacteriological laboratories extending over a period of many years. Experimental studies made by the authors at the surgical research laboratories of Columbia University, the Mayo Clinic, New York University, and also at the Rockefeller Institute and Cornell University, formed the frame work upon which these further studies have been based.[10, 11, 12]

The following pathological conditions have been observed in one hundred laparotomies in 93 patients.

Cecocolonic delay of from four to seven days duration has been the most common finding. This condition was found to be due to several causes, the most frequent of which was obstructive constriction the result of pericolic membranitis. In this condition the colon in the region of the hepatic flexure was found to present the typical "elbow deformity" already described by us. Usually the constriction was the result of bands of connective tissue of more or less density which in many intances were congenital in origin, due to failure of fusion and other developmental defects. They were certainly materially altered in character owing to long continued infection from the wall of the colon. In fact these developmental defects may be their inhibitory action predispose these areas of the colon

Fig. 4.—Roentgenogram showing the result of resection of the ascending colon.

to infection. And the frequent presence of stellate scars in the membrane in the vicinity of the known areas of infection, notably the appendix, proves the presence and effect of continued infection. Frequently added to the congenital defects are found

the recent bands of adhesions; organized products of inflammatory exudate.

In this connection we wish to call attention to the importance of the periodic intestinal obstructions due to rotation of a dilated cecum which has a common mesentery with the ileum, through an arc of a hundred and eighty degrees or more, pivoting upon its constricted attachment at the hepatic flexure. We are convinced by our long researches on intestinal obstruction as well as by the researches of others, notably Whipple[6] who has isolated a toxic protose which he considers the lethal agent in obstruction, that in addition to the bacterial infections there are present autogenous toxins due to the obstruction itself and originating probably in the intestinal epithelium. The cecum and the ascending colon are the portions which are the most frequently involved. Usually these parts are very much enlarged and occasionally a typical mega cecum is found. The dilatation is probably due to a dual cause. First chronic infection of the tissues which we have proven to be present (see Fig. 1), and second, long-continued muscular

Fig. 5.—Typical distribution of the glands about the ileocolic and ascending colic vessels.

efforts to overcome the localized obstructions referred to.

In a very small proportion of cases there is ileocecal sphincteric insufficiency, a condition recently brought into prominence as a cause of gastrointestinal invalidism. In our series this has always been associated with extensive changes of the colon and we regard it simply as one of the manifestations of a diseased colon and one of the objective symptoms useful in diagnosing the primary pathological condition. (See Figs. 2 and 3.) In every case where this has been found it has been necessary to resect the ascending colon because of other lesions in this region. (Fig. 4.)

That sphincteric insufficiency is not productive of disease is shown by the fact, first that no damage is done by the leakage which sometimes follows a lateral anastomosis, after ileocolonic resections, and second by the fact that infections never travel through an open tube, but always through the lymphatics or blood vessels; renal infection never reaches the kidney through the ureter, or pyosalpinx through the uterine lumen.[7, 8, 9]

A chronic infected appendix alone may be the only focus of infection in the intestinal tract, but it is usually found associated with other lesions. In 29 patients a chronic appendix was removed and in 10 cases no other lesion was found. Of this number 7 have apparently recovered as a result of the operation. Five of them were classed as mild manic types with frequent remissions, but usually unable to leave the hospital in the intervals. They could be classed as the chronic forms of manic depressive insanity. Two cases were classed as dementia præcox.

In the remainder of the cases of our series appendicitis has been usually associated with chol ecystitis and ovarian and tubal infection.

Involvement of the descending colon and sigmoid has been relatively rare, but it has occurred in 6 cases in our series. The usual findings have been a redundant obstructing sigmoid. It was so long in these cases that it could be brought up to the sternal notch at the time of operation or before operation upon a long sigmoidoscope. This condition is usually indicated in the x-ray plates, especially the enema, and these mega sigmoids are frequently diseased, often presenting areas of segmental infection with extensive mesenteric adenitis.

One of our cases presented an unusual condition in that there was a dense band of adhesions extending from the left adnexa to the left parietal wall, being attached to and constricting the pelvic colon at about its center. After sigmoidectomy the constricted area was found to be the seat of typical segmental infection, described by us in previous reports. In addition, this case presented an exceedingly short descending colon and the splenic flexure was on a level with the hepatic flexure. As suggested by the x-ray, this area was the seat of partial obstruction which at operation was found to be caused by a very extensive pericolic membrane. At a previous operation on this patient the pylorus was found to be nearly occluded and the gross condition of the tissue justified a pylorectomy, which was done. A microscopic study of the pylorus tissue showed vast numbers of bacteria which had penetrated beyond the epithelium. (See Fig. 1.)

The stomach in this series has shown the usual freedom from gross pathological lesions although the patients had complained of "stomach trouble." In two cases (the one mentioned above) gastroenterostomy was necessary, in one because of the pyloric obstruction and the other because of a duodenal ulcer.

Cholecystitis has occurred in ten cases, in all of which but one calculi were present, and cholecystectomy was done. We consider this procedure preferable to cholecystostomy because of the proven presence of extensive infection in all our cases of cholelithiasis.

By far the most interesting gross pathological findings in our series has been the occurrence of extensive enlargement of the mesenteric glands. (Fig. 5.) While this has not been a constant finding, however, it has been present in most of the cases of this series and certainly occurs much more frequently than in general surgical practice. We have observed that these enlarged glands occur in two large groups; namely at the ileocecal region and at the beginning of the jejunum, the former

region being more frequently involved than the latter and the one fortunately lending itself to surgical intervention. In some cases the glands are involved throughout the mesentery of the entire tract. The enlargement of the mesenteric glands is of pathological significance in that they are almost all found to be infected either with colon bacilli or streptococci and in most cases both. They are indicative of bacterial seepage through the epithelium of the gut and we have come to look upon them as indicators of the region of focal infection. When of the segmental type and suitably located; *i. e.*, in the region of the cecum and colon, the infected tract can be removed surgically. However, when the distribution of these enlarged glands is diffuse, involving the entire tract, the removal of the infection cannot be accomplished by surgery but vaccines and serums must be given to produce results.

The study of the mucosa of the excised portions of the colon usually reveals distinct gross changes varying from minute pin point areas of infection to small irregular ulcerations. Frequently hemorrhagic areas of varying size and shape are seen. Microscopic examination shows extensive changes in the epithelial and muscular coats.

Results.—While this paper is intended primarily to show the frequency of pathological conditions in the abdomens of the insane, it may not be out of place, without making any definite claims for the methods outlined, to state the results of the work on the mental condition of the patients upon whom we have operated. The procedures followed in this investigation fall into two large groups.

The first group required developmental reconstruction of the colon resection of the terminal ileum cecum, ascending colon and part of the transverse colon, and in a few cases resection of the descending colon and sigmoid. The accompanying table will show the number of cases and the mental types involved, and the condition after operation.

APPENDECTOMY, WITH OOPHORECTOMY AND CHOLECYSTECTOMY.

Mental Disease.		Re-covered.	Much Im-proved.	Im-proved.	Not Im-proved.	Died.
Manic-depressive..	13	5	5	1	2	
Dementia Præcox	14	2	2	2	8

Totals	29	7	8	4	10	

DEVELOPMENTAL RECONSTRUCTION OF THE COLON.

Mental Disease		Recovered.	Much Improved.	Improved.	Not Improved.	Died.	Recent.
Manic-depressive	15	5	2	0	1	5	5
Dementia Præcox	26	5	2	2	2	9	6
Retarded	7	3	2	1	0	0	1
Paranoid Cond.....	2	0	0	0	0	0	2
Totals	50	10	6	3	3	14	14

The second group, because of a limited involvement as indicated by the character of the glandular involvement and the lack of other evidence, required no resection, simple appendectomy being considered sufficient. In a certain proportion of these cases cholecystectomy and oophorectomy were necessary. The total number of cases in which developmental reconstruction was performed was 50. Of this number 10 recovered sufficiently to leave the hospital. Of this group 2 were classed as manic-depressive insanity, acute psychoses, and 5 were classed as dementia præcox.

While the mental diagnosis is not important we have given these diagnoses, but it would be just as well as for the purposes of this paper to classify them as acute and chronic psychoses. In the chronic group 26 cases have undergone developmental recontructions, and of this number 5 have recovered. A rather small percentage, but not to be wondered at when the type of cases and the duration of the psychoses is to be considered. Nine of this group died and it is interesting to note the cause of death, as it has a direct bearing on the whole question of etiology. The most definite finding at autopsy in these cases was a chronic myocarditis, a condition which led to impaired capillary circulation and a failure to repair at the anastomosis. Moreover, the infected portion of the gut often extended beyond the point of anastomosis and the infected area failed to unite. The total mortality for the whole group was 14 or 28 per cent. We have recently reported a series of reconstructions of the colon in general surgical practice showing a mortality of 7.7 per cent. As the technique used and the operators were the same this discrepancy indicates a much lower vitality among the insane and points to a higher degree of infection among them. Six cases showed considerable improvement, though not enough to be discharged.

The results in the second group, which includes the appendectomies, oophorectomies, and cholecystectomies, were as follows: Twenty-nine cases were operated upon which included 13 cases of manic-depressive types and 14 dementia præcox cases. Five of the former recovered and two of the latter and eight of the latter were not benefitted. It is significant to note that there has been no mortality in this group in contrast to the group of reconstructions. The number of cases in which the operation of the first group (reconstruction) which were not benefited is 3 or 7 per cent., and those not benefited in the second group were 10 or 34 per cent. This shows that the infection is probably not limited to the appendix, or that the damage to the cortex was of such a severe nature that removal of the infection had no influence on the mental condition.

The results of this work among the insane, while not to be considered startling, are at least encouraging and indicate the necessity for the early recognition of these pathological conditions in the abdomen. In all probability, if these conditions were recognized and relieved years before, many of these cases would never have been committed to a hospital for the insane. Whatever the final outcome, this preliminary work shows that the insane are replete with intraabdominal pathology and this must constitute the strongest possible plea for the institution of modern diagnosis and treatment among them.

We acknowledge our indebtedness to the medical staff of the hospital and the laboratory assistants for invaluable cooperation and help.

THE MAXILLOFACIAL SERVICE AT A. R. C. M. H. NO. 1, A. E. F., FRANCE.

By W. T. COUGHLIN, M.D., F.A.C.S.,

ST. LOUIS, MISSOURI.

PROFESSOR OF SURGERY, ST. LOUIS UNIVERSITY; RECENTLY LIEUTENANT-COLONEL MEDICAL CORPS; CHIEF OF MAXILLOFACIAL SERVICE AT A. R. C. M. H. NO. 1, AND LOCAL CONSULTANT IN MAXILLOFACIAL SURGERY FOR THE PARIS AREA.

ALMOST every physician in America has heard or read something about the American Ambulance at

FIG. 1.—"They came to us in the early days direct from the field." Pvt. K.—High-explosive shell-wound of face, fracture of mandible, "two-thirds of the upper and nearly all of the lower lip missing."

Paris. Its title while we were there was "A. R. C. M. H. No. 1."

If your thoughts turn back to the early days of the war in 1914, you will remember how the cry came over here, that thousands were dying for lack of medical attention in practically all of the warring armies. And you will remember that in almost all parts of this country, members of the medical and

can Colony in Paris, aided by a group of philanthropic individuals in the Eastern United States, wishing to do something worth while for the relief

of human suffering and in particular for invaded France, organized and equipped the institution known as the American Ambulance and decided to locate the same as near Paris as possible.

Neuilly-on-the-Seine, just outside the western

Fig. 4.—"The first indications were to relieve pain to place bone fragments in as nearly normal position as possible and hold them there—to provide for drainage." Randles—Sixth Marines. "The right lower half of the face is blown away. The right lower jaw is much comminuted—all the right upper and lower teeth to lateral incisor are missing." The fragments were fastened to each other with wire and suspended to a wire held in place by being fixed to the remaining sound upper teeth.

gate—Porte Maillot—of Paris, was chosen as the site for their hospital and the promoters of the project were so fortunate as to obtain for their purpose the "Lycée Pasteur," a high school then in course of construction. With slight alterations, this building was fitted up as a hospital, with bed accommodation for about six hundred patients.

It was at first thought feasible to have a staff composed of several small units or services, furnished by various hospitals or schools in the United States. This was found not to work out well, and finally it was decided to have the University of Pennsylvania assume full responsibility, and Dr. James P. Hutchinson of Philadelphia became surgeon-in-chief.

From the beginning the institution had boasted a Maxillofacial service, and long before we entered the war many of us had become more or less familiar with the fact. The character of the work then done was of the highest type, as a visit presently to the Army Medical Museum at Washington will prove. The dental part of the work was taken care of by Doctors George B. Hayes and William Davenport, both of Paris, who were founders of the hospital. And Dr. Hayes was still in charge when the hospital was taken over by the Army and remained director of his department until the place was closed in February, 1919.

Shortly after the entry of the United States into a state of war with Germany, the directors of the hospital offered their institution to our Government and soon afterward it was taken over by the Red Cross for the Army and became known as American Red Cross Military Hospital No. 1. Its capacity was increased to 1,500 and later to 2,400 beds, and Dr. James P. Hutchinson (now Colonel Hutchinson) became commanding officer.

Just what kind of "Cross" in military hospitals it was, I cannot make quite clear, but you will understand me when I say that the former staff remained, having all accepted commissions and that the nurses either remained as "voluntary aids" or became Red Cross nurses. Of course other officers and nurses came later, but those formed the nucleus.

The hospital was indeed singularly well equipped. I do not remember having had to ask twice for anything necessary to the comfort of the patient. For this all credit is due to those noble American women who first to last devoted themselves heart, soul, and body, purse and purpose to the great work, lived with us and worked with us—and they and the others had been doing it for four years when we came! Without them, "the Ambulance would not have been." I refer particularly to Mrs. Vanderbilt and Mrs. Munro.

Four of the members of the oral and plastic unit of Major Blair, myself in the number, were detailed on our arrival at Blois in April, 1918, to duty in Paris for observation of methods there and were stationed at "No. 1." At that time the hospital had a staff competent and sufficient for its needs, the Maxillofacial service being under the care of Maj. Charles A. Powers of Denver, who was later forced to return to the United States on account of illness.

About the end of May, however, the attacks at Compiègne and Cantigny caused a rush at the hospital, and the "C. O." sent for us and put us to

Fig. 5.—Same patient as pictured in Fig. 4, showing how he looked when he left; no bone graft was needed but there is much new bone in the jaw, firm consolidation.

work. Captain Lankford (later Major Lankford) of Baltimore became the ranking officer in the dental department, although Dr. Hayes remained as director. The equipment of this department was rather better than that of any first-class dental

school that I have ever seen. The mechanical department was under the direction of Mr. Moore, who had been there with Doctors Hayes and Davenport since the beginning, and one can form some idea of its importance from the fact that army

FIG. 6.—"A loop of thread passed through the tongue rendered tracheotomy unnecessary." Louis B.—Total loss of chin, bone loss from right third to left second molar.

men were sent here for instruction in the making of appliances for use in maxillofacial reconstruction. Here as elsewhere in the hospital were to be found all of the modern apparatus that one could find anywhere for convenience in carrying on the work.

Our patients were mostly Americans, but a large number of French were also treated. Both came to us in the early days direct from the field or from hospitals nearer to the front, practically

FIG. 7.—"Shrinkage was prevented by hooks and elastic traction." The same patient seen in Fig. 6. The projector is fastened to the splint on upper teeth made and applied for me by Captain Lankford, D.C. (See *Dental Cosmos*, Sept., 1919.)

all coming within four days after the injury; later, as the front receded, the time between their being wounded and their admittance was longer, but hardly ever more than ten days.

The injuries to the face and jaws varied from the most trivial to the gravest, as varied also the complicating injuries.

The ward for face-and-jaw cases was on the top floor and contained fifty-five beds. It was occasionally necessary to overflow this into a general

FIG. 8.—I think that seldom is there "total loss of soft parts." The same patient seen in Figs. 6 and 7 as he looked when he left us.

surgical ward on either side, and we always had a few of the less severe cases in the various wards throughout the house.

Patients on admission were sent to the O. R., where such treatment was given as seemed indicated. Only rarely was one admitted who seemed in danger of immediate death—not more than half a dozen in all. When this did happen the case was always (except in one instance) "suffocating phlegmon," or acute sepsis, due to the attempt of some one farther up the line to secure healing by first intention without making ample provision for drainage. The trouble was rectified by removal of sutures, and cleaning out and packing recesses.

In cases with large losses of substance, whether bony or soft parts, the first indications were to relieve pain, to place the fragments of bone in as nearly as possible their normal positions, to hold them there, to prevent as far as possible shrinkage of soft parts, and to make provision for drainage. We never found it necessary to do a tracheotomy. A loop of silkworm gut passed through the tongue was the only measure ever needed to prevent the tongue from dropping back after loss of the chin. The shrinkage of soft parts was laregly prevented by the use of hooks and elastic, care being taken that *too much* elastic traction should never be used. This principle we made use of to a great extent and Fig. 5 illustrates a method we resorted to, in order to prevent shrinkage of the flaps after a "total loss of arch of mandible and overlying soft parts." I am convinced that very seldom is there "total loss of overlying soft parts." Rather do I believe that the remaining soft parts are allowed so to shrink, while the wound is healing, that it comes to look as though the soft parts too had been blown away.

The device shown in Figs. 5 and 8 was made for me by Major Arthur Lankford, D. C., of Baltimore, and has been described by him in the *Dental Cosmos* for September, 1919. The method and the device are, so far as I know, original.

Fig. 9.—Elastic traction to pull forward posterior portion of body of jaw after cutting the ascending ramus on level with upper border of body, in order to bridge a loss of substance in left canobicuspid region. I was not strong enough to pull it forward at operation so closed the defect in soft parts and attached wire to bone and elastic to wire; got firm union.

Many wounds of the upper face were closed after excision—and in face wounds I never excised more

Fig. 10.—"The plastic operations for repair were undertaken when healing was complete." Pvt. K.—306th Inf.—Shell-wound of face. The anterior wall of antrum is missing.

than a very thin layer—usually with a few strands of silk worm gut or a strip of rubber for drainage. They healed kindly. If, however, there were already signs of infection in the wound, no closure was done; if suturing had been done all sutures were removed and the wound was explored, cleaned out, and either packed lightly with iodoform gauze or "Carrel-Dakinized."

Wounds involving the floor of the mouth or the

Fig. 11.—Shows same patient pictured in Fig. 10, after both bone and fat transplant; the operation wound has just healed.

lower part of the pharynx, we always packed lightly with iodoform gauze, preferring to take the chance of having the patient get well with a fistula rather than that of having him die of sepsis or secondary hemorrhage.

At each patient's bedside was a small table on which stood a short wide-mouthed bottle and an ordinary ½ oz. glass syringe. All wounds involving the mucous membrane of mouth or pharynx were syringed every hour by day and every two hours by night, during the acute stage. We tried potassium permanganate, 1-2000; normal saline, 5 per cent. salt solution, and Dakin's solution. Of all, I liked the Dakin best and its use during the first days became routine. I never saw it irritate a mouth or throat in less than six days. After five days we alternated between Dakin and potassium permanganate, 1-2000, and after the third week we used the Dakin less and the potassium permanganate more frequently. When patients became able to thus care for themselves, the onus of doing so was placed on them. There never was any stench in our jaw ward; when a mouth case is allowed to become foul smelling the "oral surgeon" needs more general training.

Of complications we had quite a few. Pneumonia was responsible for four of our six deaths. Two of these patients had been gassed and two had complicating gunshot (or shell) wound of the lung and all had fractured jaws—in fact every case of fractured jaw complicated with penetrating or perforating chest wound or "gas bronchitis" died. Secondary hemorrhage occurred three times, once the inferior dental, once the facial, and once the external carotid. In this last case death followed ligation of the common carotid. Our other death was due to meningitis—a small piece of shell in the corpus callosum.

Three patients showed polyarthritis and tenosynovitis; in one three joints suppurated and had to be opened—streptococcus infection. All recovered without loss of function, under the Willems treatment. Erysipelas appeared four times, the first case

Fig. 12.—"Plastic work—bone and fat grafts were done, etc." Pvt. V.—28th Inf.—The lower margin of the orbit and a portion of bone in front of antrum are missing. There is a marked ectropion.

had recrudescences and was isolated more than a month; the others got well in less than six days. (I had about eight severe cases of erysipelas including

Fig. 13.—Shows the same patient seen in Fig. 12, after free bone and fat grafts had healed in place.

the last three mentioned, all of which I treated with increasing daily doses of antistreptococcic serum, none of whom had recrudescence.)

Acute phlegmon (staphylococcus) of the side of face and neck developed once—a consequence of misguided effort, an attempt made to drain an acute abscess through non-inflamed tissue—mea culpa. This was the only case in which an infection of face or neck spread after coming into our service.

The fractured jaw was immobilized as soon as

Fig. 14.—"If there were signs of infection and suturing had been done all sutures were removed, etc." Pvt. P.—Shell passed in through the wound seen, carried away 3 to 5 cm. of the jaw and ploughing across in front of the epiglottis under the tongue, comminuted the other side of the jaw. This wound had been closed almost entirely by drawing the superficial structures together. We nearly lost him through secondary hemorrhage the day after he came in.

possible after coming in. Sometimes it was necessary to wire the teeth for a few days, as owing to stress of work it was impossible to apply splints immediately. Only once I think was a patient evacuated without fixation, and this one was evacuated by the evacuating officer through mistake, very shortly after he was admitted. The permanent splint was of the gutter type. When all teeth were loosened or missing and the jaw was much fragmented, recourse was had to wiring of fragments to each other and suspending from the teeth in the upper jaw with some sort of support from below held up by means of a head gear. We did not "immediately establish dependent drainage in all fractures of the jaw." But if signs of infection at the fractured site appeared, drainage was then at once established. Teeth involved were not "always at once removed" but it was our aim never to leave an involved tooth in place longer than three weeks unless union was taking place. The same was true with regard to fragments of bone; even when quite loose they were allowed to remain for three weeks at least; of course, abscesses were not allowed to form around either teeth or fragments—irrigation and drainage combated that. There was not a case in our service that failed to unite without operative intervention except in patients who had suffered a total loss of more than 1 cm. in length of the bony substance; and several where at first there was apparent total

loss of more than 2 cm. in length have to-day solid jaws and good occlusion without any kind of operative procedure.

Generally speaking we used the closed bite splint, but in certain bilateral fractures in the anterior

Fig. 15.—"Our splints were of the simplest type." Pvt. L.—American treated in an allied hospital for some two or three months. The case is one of fracture of mandible with loss of substance from molar region to molar region. In addition to the external apparatus there is a very complicated arrangement inside which almost fills the mouth. The picture shows the condition on entering our service.

half of the body of the jaw the open bite was used. When the fracture was unilateral (or mesial) and solid teeth were present on both sides of the fracture, a gutter capped the teeth of the entire jaw and after a few days' closure, the patient was allowed to use the jaw. All patients as the mouth was opened were made to chew gum of which, thanks to kind friends, we usually had an abundance. No case of uncomplicated fracture developed trismus.

When the upper jaw was fractured and the antrum or nasal chamber was involved the rhinologist was at once placed in charge of his aspect of the case, and it is due to the skill and treatment of Captain Tucker, M. C., that not a single case of empyema of the antrum occurred. The irrigation of the nose and antra or other sinuses was not done with Dakin's solution—we used Dobell's solution instead. The splints were again the gutter cap to all of the teeth after reduction. Only in two or three cases was it necessary to use any kind of head-gear support. In fact one case of craniofacial separation—one could see the landscape through a hole transverse just below the level of his orbits—got well without any splint at all and has very good occlusion. Some received a week or more after the injury were difficult of reduction, but our dental colleagues with traction and pulsion were, except in two cases, able to accomplish it without any open operations.

The plastic operations for repair of soft-part defects were in the main undertaken just as soon as healing of the wound had occurred. We never noticed that infection was "stirred up" by this procedure. We tried some early plastic repair while wounds were still unhealed, but the results were not at all gratifying. In only one case was a general anesthetic used. I prefer novocaine and adrenalin with morphine and atropine, scopolamine, or hyoscine preliminary. Even bone graft, free or pedicled, cartilage grafts, as well as fat graft and epithelial inlay, were all done with local anesthesia. I do not believe that local anesthesia *per se* favors infection any more than does the presence of onlookers.

Of course excision of wounds, incision of inflamed areas, removal of foreign bodies, etc., in fact, all operations except the plastic operations were performed under general anesthesia, ether, "Rausch" gas and oxygen, gas and ether, ethyl chloride, and De Page's mixture were all used and for short operations in this work, as in general work, I used ethyl chloride by preference.

In all I should estimate that something over three hundred cases passed through our service from April, 1918, to February, 1919. We received the wounded of our allies as well as our own and always had a large percentage of French soldiers. Our service became the "center" for the Paris area about the end of September or the first of October, and the more serious cases from the other hospitals in this area were sent to us.

Any success that our service may have attained was largely due to the hearty and painstaking collaboration of our colleagues of the Dental Department and to the untiring attention lavished on our

Fig. 16.—Shows the same patient pictured in Fig. 15. one week later. His fragments are firmly held in normal relation to each other and to the upper jaw. His jaws are not fastened together. No dressings were used, but no scales or crusts were allowed to form.

patients by our nurses and our volunteer aids, while the interest and desire to help on the part of everybody surely encouraged and stimulated us to our very best efforts.

University Club Building.

HOME VS. HOSPITAL CARE OF CASES OF INFLUENZA.

By L. EMMETT HOLT, M.D.,

NEW YORK.

THE prevailing tendency of the times, and we believe a wise one, is toward the larger and larger use of hospitals in all surgical conditions. This is most desirable because in few homes, except those of the wealthy and sometimes not even there, is it possible at the present time to secure the conditions which are essential to good surgical results.

Many have urged the greatly increased use of hospitals for acute medical cases as well, and some look forward to the time when most of the cases of serious illness will be treated in hospitals, except perhaps in homes where the services of one or sometimes two trained nurses can be afforded for a single patient. But at present and for a long time to come most sick people must be treated in their homes. Even if it were desirable, it is simply impossible for any city or community to provide enough hospital beds to supply the need. It has been estimated that fully 90 per cent. of sick people are treated in their homes as against 10 per cent. treated in hospitals.

The possibility of taking proper care of very sick patients with only part time service of a trained nurse is not yet generally appreciated either by the medical profession or the public. With the present shortage of nurses and the expense involved in the full time of one or possibly of two nurses, the service of the part-time visiting nurse would seem now the best solution of the problem rather than to seek to provide for them in hospitals.

The advantages of hospital treatment are many and obvious. More accurate diagnosis is possible. As physicians and nurses are constantly within call, emergencies which arise may be more promptly and more capably met. Furthermore, in certain diseases, as in cerebrospinal meningitis and some forms of acute pneumonia, the special treatment required is difficult or impossible of application in most homes.

But there are disadvantages in hospital treatment as well and these also must be considered. Not only is this true if the patients are young children, but of adult patients. When many sick patients are brought together in even our best equipped hospitals conditions are created which are prejudicial to the patient's chances of recovery. This is particularly true of respiratory infections and our common communicable diseases such as influenza, measles, scarlet fever, and diphtheria. The frequency and the severity of complications and the mortality of all these diseases is increased just in proportion to the crowding together of patients. Witness the mortality of measles when epidemic in foundling asylums or large institutions for children. This was emphasized again by the experience in the army camps. Here measles proved to be one of the most difficult medical problems encountered, on account of its severity and frequent complications.

Epidemic influenza is another disease in which precisely similar conditions obtain. In this also the frequency and the severity of complications and the high mortality from this disease as everywhere reported appears to have been directly in proportion as many patients were brought together.

The statistics of the epidemic of influenza in the fall of 1918 which have been published have been largely those of civil and army hospitals. The mortality in camp hospitals and on army transports was something awful. It is difficult to obtain from private practice of any physician a sufficient number of cases which would furnish figures by which a comparison might be made between cases treated in their homes and those treated in the general hospitals.

The statistics of the Visiting Nurse Service of the Henry Street Settlement furnish some very interesting data which bear upon this question. As a member of the Board of Directors of that Institution these statistics were at my request turned over to me for study and analysis, and I have found them most illuminating. They make one pause who would advocate sending cases of influenza or all cases of pneumonia to hospitals for treatment, even though the home surroundings are far from good.

The homes in which the cases visited by the nurses occurred were very few of them among the well-to-do; as a whole they represent perhaps the better class of the tenement population, including, however, a very considerable number of the very poor. Small apartments and crowded tenements were the environment of these patients with very few exceptions.

During the epidemic which occurred in October and November of 1918 the Henry Street Settlement had on duty 162 nurses. The calls for the visiting nurse usually came from physicians or from members of the family. All of the patients treated, however, were under the care of physicians.

Daily visits were made to all acute cases and to some of those most seriously ill two visits were made by the nurses. Moreover, during the height of the epidemic, night visiting nursing service was introduced from five different stations in the city. In a small number of cases a special nurse attended the patient. This intensive care was given to the pregnant women. The medical treatment differed widely, as the cases were under the care of many different physicians.

The total number of influenza and pneumonia cases visited and reported upon during the epidemic was 10,365. There are excluded from the analysis in this report 1625 cases for the following reasons:

Recovered before the nurse arrived	628
Mild cases, not requiring subsequent visits	450
Removed to hospital before the nurse's visit	125
Died before the nurse arrived	85
Not treated as a special nurse was on the case	328
Total	1625

The mortality of the remaining 8740 cases is shown in the following table:

TABLE A.

Type of Case.	Number Treated.	Deaths.	Per Cent. Mortality.
Influenza	6243	115	1.6
Pneumonia	2497	485	19.4
Total	8740	600	6.9

In the following table is given the classification by ages of the influenza and pneumonia cases respectively with the mortality:

Table B.

Age.	Influenza			Pneumonia			The Two Combined		
	No. Cases.	Deaths.	Per Cent. Mortality.	No. Cases.	Deaths.	Per Cent. Mortality.	No. Cases.	Deaths.	Per Cent. Mortality.
0– 5 years.....	1648	23	1.40	669	105	16.0	2317	128	5.5
6–15 years.....	1822	8	0.40	401	34	8.5	2223	42	1.9
16–20 years.....	327	5	0.15	129	38	30.0	456	43	9.4
21–30 years.....	1150	44	3.60	729	168	21.0	1879	212	11.3
31–40 years.....	756	18	2.40	356	89	25.0	1112	107	9.6
41–60 years.....	437	11	2.20	183	42	23.0	670	53	8.0
Over 60 years....	53	6	11.50	30	9	30.0	83	15	18.0
Totals.....	6243	115	1.60	2497	485	19.4	8740	600	6.9

It has been a general observation that the cases of influenza which occurred at the beginning of the epidemic were not so severe, but that the disease increased in severity for the first week or two and then slowly diminished. It is interesting, therefore, to observe in this group of patients how the mortality was affected by the period of the epidemic in which the cases occurred. In the following table there is given the mortality for the different weeks of the epidemic of both influenza and pneumonia cases. The week in which the case is grouped is that in which the first visit was made.

Table C.

	Influenza.			Pneumonia.		
	Cases.	Deaths.	Per Cent. Mortality.	Cases.	Deaths.	Per Cent Mortality.
1st week...	262	2	0.76	101	22	21.8
2d week...	765	18	2.30	243	78	32.1
3d week...	1142	15	1.30	388	109	28.1
4th week..	2177	60	2.80	783	154	19.7
5th week..	872	16	1.80	371	73	19.7
6th week..	518	3	0.58	263	28	10.7
7th week..	293	.....	.....	184	9	4.9
8th week..	214	1	0.47	164	12	7.4
	6243	115	1.60	2497	485	19.4

In Table D are given the deaths from influenza and pneumonia combined, together with the percentage mortality at different periods of the epidemic:

Table D.

	Cases.	Deaths.	Per Cent. Mortality.
1st week.....	363	24	6.6
2d week.....	1008	96	9.5
3d week.....	1530	124	8.1
4th week.....	2960	214	7.2
5th week.....	1243	89	7.2
6th week.....	781	31	4.0
7th week.....	477	9	1.9
8th week.....	378	13	3.4
	8740	600	6.9

From this it would appear that the highest mortality was in the second and third weeks of the epidemic and that the mortality gradually diminished during the last weeks.

Statistics have been published from many institutions showing the very high mortality which occurred among pregnant women. I have seen none given which referred to any except those which occurred in institutions. In Table E are given the figures regarding the pregnant women in this series of cases observed:

Table E.

	No. Cases.	Recovered.	Died.
Total pregnant cases.....	154	133	21
Pregnancy not interrupted.....	94	79	15
Abortions and miscarriages.....	13	7	6
Premature labor (eight months).....	1	1	....
Full-term labors.....	46	46	....

The statistics which are presented in the foregoing tables, while they are not large compared with those reported from army camps and from some of our largest hospitals, fully bear out the general impression that cases of simple influenza and influenzal pneumonia are best treated in their homes or when separated as much as possible. They also indicate that the frequency and the severity of all complications are much increased just in proportion as patients are crowded together.

Since this report is from the records of nurses and not a report from physicians in attendance, very many points of accurate classification in the data are not given in this report. Yet a sufficient detail is given to warrant the conclusions which we have drawn above.

It is unfortunate that most of our medical statistics have been drawn largely or almost exclusively from cases treated in institutions; and it is of course difficult for any one physician in an epidemic to care for a sufficiently large number of cases for his observations to be of great statistical value. It is for this reason that these figures have been presented, as the opportunities for observation were in many respects somewhat unique.

While it may be urged that only the more severe types of the disease are sent to a hospital and that the mortality figures of such institutions do not represent fairly the actual mortality from the disease, it may with equal truthfulness be said regarding the statistics which are here presented that they also represent only the more severe forms of influenza; for at the very outset of this report it has been stated that no less than 1087 cases, or about 10 per cent. of those to which the nurses were called, have for this reason been excluded from the analysis of this report. Such cases had either progressed so far toward recovery or were of such a mild character that a second visit by the nurse was considered unnecessary. The demand for the services of the nurses during the epidemic was so great that only those cases which actually required the nurse's attendance were visited, the others being left to the care of members of the family.

THE CONTROL OF CANCER.

AN APPEAL TO THE PRACTITIONER.

By F. T. VAN BEUREN, JR., M.D.,

New York.

In the first place, may I remind you of what is now very generally accepted: that there has been an enormous increase in the mortality from cancer, during the past fifty years, practically all over the world; and that, last year, cancer killed more than 61,000 people of these United States in the registration area alone, and over 9700 in New York State.

It is idle, of course, to speculate upon how much of the increase in the cancer death-rate is real and how much is due to better final diagnosis. It is statically valuable, to be sure, but it is of little use to the dead man to know what he died of. We must learn to know what is threatening his life, long before he even begins to die, if we are to be of aid to him.

We do not want to make the correct diagnosis final, we want to make it early. That this is the real crux of the whole matter cannot be denied whether you adhere to Bloodgood's Gospel of the "precancerous" condition or profess merely the more conservative belief that every cancer is, in its early stage, a purely local condition, and, in that early stage, susceptible of cure by complete removal.

The latter is, without question, accepted as true by all the foremost exponents of modern medicine. And this early removal is, like all the other procedures of modern medicine and surgery, strictly speaking, a preventive measure. For, by way of example, we have to admit that the most perfect development and application of aseptic surgical technique does not heal a wound. It merely prevents the infection that would delay its repair.

And so, if you like to play with words, early removal does not cure the cancer; it cures the patient. But to effect the cure, the removal must be early and the diagnosis earlier still. This necessity for earlier diagnosis is splendidly illustrated by the researches of the commission on cancer of the Medical Society of the State of Pennsylvania, who, in 1910 and 1912, tabulated the record of 400 cases of cancer and found that the patients who had superficial growths came to operation (on an average) 14 months after noticing the first sign of the disease.

They found also that about half the cases, superficial and deep alike, had had some form of chronic irritation or "precancerous" condition such as ulcers, uterine tears, etc. "So that," the report continues, "one-half of the cases that apply to Pennsylvania surgeons need not ever have had a cancer if they had known the significance of this precancerous condition and had it remedied before cancer developed."

More important still for us, however, their tables showed that, in the cases of superficial cancer, the patient's physician had known of the condition present for an average of *one year* before the patient came to operation; and, in the case of deep seated cancer, the patient's physician had known of the condition for an average of *over* 13 *months!*

Now, when you consider that, in many cases of cancer, death follows within 36 months after the first symptom noticed by the patient, I think we can agree that we ought to allow somewhat less than one-third of the remainder of their lives for making a diagnosis.

Gibson, Professor of Surgery at Cornell, read a very suggestive paper, not long ago, in which he analyzed the condition and course of 110 cases of cancer cared for at the New York Hospital from February, 1913, to April, 1915. Basing his classification upon the conviction that the majority of cancers are for some time purely localized, and at that time curable, he stated that, on account of the advanced condition of the disease, only 11 could be promised a reasonable expectancy of cure, 6 were doubtful, and 93 (84.5 per cent of the whole) offered no probability of cure whatever!

In the last 28 consecutive cases, where special efforts were made to obtain details of the opinion or advice received by these patients from the first doctor consulted, the evidence showed conclusively (he says) that at least 50 per cent of them had received no advice or treatment based on recognition (or even suspicion) of their condition! As examples of this fact he cites a number of cases, stating the improper treatment that they had received. "The deplorable percentage of hopeless cases," says Gibson, "coupled with the investigation of the kind of advice given many of these unfortunates justifies me, I believe, in accusing our profession as responsible for a large proportion, perhaps the majority of lost opportunities successfully to treat probably curable conditions."

This is the judgment pronounced upon the medical profession by one of its leaders in New York City; and Kelly and Neal of Johns Hopkins, Chauta and Wertheim of Vienna, Taussig of St. Louis, Novak and Bloodgood and others corroborate the sort of evidence upon which it is based.

This is a very broad indictment and I am not sure that all of you will agree that it is a just one. But at any rate, it raises at once the useful question, "What are you going to do about it?" Why! we are going to do this— we are going to instruct ourselves in the best methods of early diagnosis of cancer and we are going to teach our patients to come to us early for diagnosis. And we are going to try to require absolute proof of the innocence of each individual case of suspected malignancy before we adjudge it not guilty.

I say suspected malignancy because it is just this type that we must concentrate our energies upon. Any second year student will cry "cancer" if you show him an extensive callous ulcer of the lower lip, a foul sloughing tumor of the breast, or a stony hard abdominal mass in the stomach region. It is not these terminal stages that must engage our more mature attention. It is the superficial erosion of the lips or tongue, the slight induration in the breast, the doubtfully enlarging skin blemish, the resistant anal fissure, the history of vague but persistent gastric or intestinal indigestion, or obstinate constipation, or the possibility of blood tinge in the vomitus, urine, stools, or vaginal discharge. For they are among those early, indistinct symptoms of cancer that are useful alike to the patient and to his physician, if only heed be given their warning. That is the point, to heed their warning. We must not wait for cancer to try and justify its pitiless fatality by claiming that we disregarded the danger signals.

Now, it is not at all the purpose of this paper to destroy your interest by a complete, accurate, and exhausting account of every possible early symptom of any possible cancer anywhere in the human body.

But it is my intention and my deep desire to implant upon your minds, as it has been implanted in my own, a rapid-growing ineradicable variety of suspicion; so that never again can any man,

who reads this, look upon an ulceration, a mole, or wart; or palpate an indurated area, or tumor mass; or listen to a history of indigestion, or constipation, or of irregular discharge, or bleeding, without having the idea of cancer present itself to his consciousness, and remain there until he has proved, as speedily as possible, and without peradventure of doubt, that no such menace is either present or impending. But, to give ourselves and our patients such assurance, we *must* listen and we *must* feel and we *must* look. For the warning still holds good to-day, that was given over a hundred years ago to his students by one of the foremost bedside teachers of his time: "More mistakes are made gentlemen," he told them seriously, "many more, by not seeing than by not knowing!"

It is in our physical examination, then; in the patient and thorough collection of evidence, that we medical men fail, rather than in our deduction from the evidence when gathered.

In this regard, says Novak, "every medical man owes it to himself and even more to his patients to learn all he possibly can, through reading, attendance at meetings, and otherwise, concerning a disease which is at once so deadly and so frequent as cancer."

Gibson, in the paper I mentioned above, says it is necessary to revolutionize the old methods of diagnosis, and adds: "The practical application of these revolutionary principles will be threefold: (1) Recognition and cure of precancerous conditions. (2) Throwing overboard all classical diagnostic formulæ, *e. g.* cancer of stomach recognized by great emaciation, pyloric obstruction, palpable tumor, and cachexia. These are terminal symptoms and consequently useless. (3) The recognition that many conditions cannot be diagnosticated in the curable stage (with any frequency) save by unusual methods. These procedures, such as exploratory laparotomy, should hereafter be classed not as extraordinary, but as legitimate measure of anticipation!"

Let these expressions and suggestions stand then, as a summary of our mistakes and of how we may learn to avoid their repetition.

But perhaps too little has been heard, in all this, about the culpability and stupidity of the patients who frequently fail to give the physician an opportunity to make an early diagnosis of cancer. Well, personally, I cannot blame them much! For myself, I have a deep sympathy in their reluctance to hear such a doom pronounced as was formerly thought inevitable.

And yet, one may object, "you would sanction, nay! advise, insist even, on counselling our patients to subject themselves to that same fear of death that comes with the suspicion of cancer?"

Why! not at all, that is just what I would not do. I would teach them there was no need to fear, *if treated early.* For "in the early recognition and treatment of cancer lies the hope of cure." That is the motto for the American Society for the Control of Cancer; and it is that which must be instilled into the mind of every patient, of every doctor, who intends to help in lowering not only cancer mortality but cancer morbidity as well.

Tell them that cancer is a curable disease; that it is even within limits, a preventable disease; and that it is fatal only if neglected. Tell them that if they will only come to you on the first suspicion of anything which might be cancer they can almost certainly be cured. Tell them it is not surgery that is dangerous (only about 1 per cent of cancer cases die from operation) but delayed surgery. And then tell them what are those conditions that may properly be termed the danger signals of cancer.

Here is the essence of what the American Society for the Control of Cancer tells them:

1. Do not neglect the treatment of persistent ulcers, sores, cracks upon the lips, cheeks, tongue, or any other part of the body.

2. Have removed any wart, mole, or birthmark just as soon as it shows any evidence of growing larger.

3. Have removed any such growth, in any case, if its situation renders it liable to continued irritation.

4. Do not neglect the treatment of chronic indigestion.

5. Secure early treatment for irritating discharges from the uterus (womb) or vagina, and have any injuries due to childbirth promptly repaired.

6. Have any broken or decayed teeth repaired or extracted.

7. Consult a competent physician or surgeon twice a year for possible symptoms of cancer.

8. Insist on getting a thorough examination when you go to a doctor for advice as to a possible cancer.

9. Consult a competent surgeon for any chronic indigestion, vomiting of blood or bleeding from the rectum, or blood noticed in the movements of the bowels. These are things which must not be neglected.

Such are the practical details that it has been agreed upon the public ought to know, in order to help us to help them. And, in your work of educating your patients, you will find the American Society for the Control of Cancer ready and anxious to help.

And now, having examined the subject; having admitted our mistakes and having outlined the means of overcoming them, and a method of persuading our patients to help us, it is fair to ask, "but will it be worth while?" Well, I am in the peculiarly fortunate position of being able to offer you the proof of the pudding before you even begin, figuratively speaking, to eat it. I said in the beginning that the death rate from cancer had increased all over the world with very few exceptions; and it is one of the exceptions that I must refer to now.

Some thirty years ago the statistics showed that cancer mortality had increased, in a part of Northeastern Germany, about 100 per cent. during the preceding 12 years. An educational campaign similar to ours was instituted and, 10 years ago, a definite reduction in the cancer mortality became observable. In the six years prior to the war the reduction had reached a point 15 per cent. below their highest mortality figures.

Not very much of a decrease, you say; no, not if

measured in units, perhaps; but as an example of what can be done; as proof of a once very doubtful theory, the aspect of that little decrease is immense. It looms enormous as a signboard pointing to the tremendous future of our work in this country.

Finally let me repeat: We do not know how to make early diagnosis of cancer? Then we must learn to! Our patients do not come to us early? Then we must teach them to do so. These are moral obligations as well as professional and lie at present most heavily upon us all.

And in this connection, there is a paragraph from a Health Bulletin sent by the Postal Life Insurance Co. to its industrial policy holders. I cannot forbear to quote it; for, though it is addressed to laymen, its admonition is far from valueless to the practising physician. It says, "While awaiting the oft-heralded but as yet elusive 'cancer cure,' give the surgeon a chance to cut the cancer death rate in half. He can do it."

Look upon the surgeon, then, as your assistant, if you will, in this great work of controlling cancer. But above all, remember to look upon any lesion that may be, or may possibly become cancer itself, only with the deepest and most critical and most obstinate suspicion.

POLYCYSTIC KIDNEY OF ATYPICAL CHARACTER.*

By LEROY BROUN, M.D.,

NEW YORK.

SURGEON TO THE WOMAN'S HOSPITAL.

In Braasch's "Clinical Data of Polycystic Kidney," read before the Association of Genito-Urinary Surgeons,in 1916, he presented the clinical findings of forty-one cases, which had had exploratory operations in the Mayo Clinic. Of these twenty-six were diagnosed as such before operation.

*Reported to the New York Obstetrical Society January 13, 1920.

Of the symptoms associated with the presence of such kidney degenerations he accentuates *pain*, *hematuria*, and evidence of *renal insufficiency* together with *increased blood pressure*.

Pain over the diseased kidney varies greatly and is dependent in part on the presence or absence of infection, due to the lack of complete drainage from the distorted kidney pelvis. It is also influenced by the extent and degree of cystic change in the kidney, resulting in a greater or less pressure on the intervening kidney structure.

Hematuria, he states, occurred in 40 per cent. of the cases and varied in duration from that of an occasional occurrence of a few days to that of several months' continued bloody urine. He explains the occurrence of hemorrhage as due to a rupture of capillaries within the cyst cavities and the subsequent emptying of the contents of such hemorrhagic cysts in the pelvis of the kidney.

Renal Insufficiency.—The involvement of one or both kidneys at the time that the patient comes under the care of the physician will determine the degree of retention toxemia of the patient. While the condition is regarded as practically an interstitial nephritis, usually advanced more in one kidney than the other. Braasch, however, points out that in most instances the first evidence of renal disturbance and occasionally the only evidence extending over a period of several years is nausea and vomiting. He states that only these symptoms were present in six out of nine cases, which showed other evidences of renal insufficiency.

Attendant cardiac disease is rare and then only as an end result. None had edema of the extremities.

The case coming under my care and reported here is as follows:

Mrs. E. W., colored, age 24 and married, was admitted to the hospital December 6. She has one child 2½ years old, and has had two miscarriages each two months advanced: one in June, 1918, and January, 1919. No previous illness.

She has some pelvic pain at the time of menstruation, also a uterine discharge, apparently referable to the previous miscarriages.

Her chief complaint, however, is pain over the left lower quadrant. This has existed for the past year and has become worse during the last six months, and especially on physical exertion.

The patient is habitually constipated. She gives no history of prolonged gastrointestinal disturbance.

She has had recurring painful urination for the past six months and states she had bloody urine six months ago, which continued for a week.

Examination.—Pelvic: A minor laceration of the cervix and perineum; uterus forward. A mild degree of endocervicitis. Both fornices are free and the adnexa cannot be felt.

Abdominal: Tenderness on deep pressure over the left lower quadrant. An abnormal tumor is felt in the upper left quadrant. This extends downward to the level of the umbilicus and well toward the median line.

The surface of this tumor is smooth and lies closely against the anterior abdominal wall. Its upper border cannot be felt on account of its extending under the ribs. Its lower border is sharply defined and the examining fingers can be easily pushed under the shelving edge of the mass. The impression is that the surface and edge of the tumor felt is that of an enlarged spleen. Heart sounds negative with exception of snappy aortic second sound. Blood pressure—systolic 145, diastolic 90. Lungs and liver negative.

Laboratory and Pathological: Cervical smears—no gonococci. Wassermann—negative. Blood—4,480,000 reds, 7,200 whites; hemoglobin, 95 per cent.; poly-

nuclear, 68 per cent.; lymphocytes, 28 per cent.; eosinophiles, 4 per cent; morphology (normal); no plasmodia under a 30 minute search.

Urine: Marked trace of albumin; pus in clumps, hyaline casts, masses of epithelial cells.

Renal insufficiency: Blood urea—40 mg. per 100 c.c. blood on the 11th and 42 mg. per 100 c.c. blood four days later.

Phthaleine test, intramuscular, 70 per cent. for first two hours on the 13th and 66 per cent. four days later.

The *urological examination* by Dr. Bugbee, urologist to the hospital, is as follows: "Urethra, trigone, and sphincter congested. Bas-fond, fundus, and ureteral orifies normal."

Ureters: Catheter in right ureter passes 30 cm. In the left passes 25 cm. Urine from the right, flow is free, clear and pale; from the left not so free, clear and pale. Phthalein intravenously began to show in right ureter at 3 minutes; in the left ureter at 5½ minutes.

The Pylograph: X-ray with catheters in situ injected with thorium: Right, small kidney pelvis with narrow major calices—practically normal; left, broad kidney pelvis with marked separation of middle and lower calices. The major calices are all very broad with ill defined minor calices. The picture may be that of an old infection or a beginning polycystic kidney.

Phthaleine intravenously: Right kidney for first 30 minutes, 20 per cent.; left kidney, 15 per cent.

Chemical and microscopic: Right—pale yellow, clear, acid, slightly bloody. Albumin. Urea 2.8 per cent. *Microscopic:* No casts, isolated and grouped red cells. Occasional isolated leucocytes; no crystals; no bacteria. Left—Pale yellow, clear, acid, slightly bloody. Albumin. Urea, 1.6 per cent. *Microscopic:* Occasional small hyaline granular and epithelial casts isolated red cells, occasional isolated and grouped leucocytes; no crystals; occasional bacteria of colon type."

The *x*-ray picture of the tumor after the abdominal cavity was distended with oxygen, brought out in clear outline the size and location of the kidney tumor with overlying spleen, which had been pushed up by the kidney mass underneath. I append the pylograph showing the broad irregular left kidney pelvis; also the *x*-ray of the kidney and spleen in the presence of abdominal oxygen distention.

As will be seen by the detailed report of the study of this renal tumor no definite knowledge could be obtained as to its character. The mobility of the mass precluded the likelihood of an old inflammatory process. The appearance of the pelvis and the major calices was not typical of a cystic kidney.

The kidney function as a whole (both kidneys) was not impaired, in fact, it was increased, ranging between 65 to 70 per cent. for the first two hours. This is in line with cases spoken of by Braasch in which the kidney function for five out of eleven cases ranged from 40 to 70 per cent. There was a small variation in the activity of the two kidneys, the right excreting the intravenous phthaline solution in three minutes and showing a 20 per cent. excretion in 30 minutes; while the left began to show the solution in 5½ minutes and gave a 15 per cent. excretion in the same time.

An exploratory operation was necessary to differentiate between a possible hypernephroma and a polycystic kidney. The kidney being exposed through a free lumbar incision it could be easily palpated. The cortex was thickly studded with numerous underlying cysts of about 2 c.c. capacity. Over the greater curvature many of these had fused into a larger cyst of about 40 to 50 c.c. capacity.

The character of the tumor having been established and on account of the slight impairment of its functioning power, it was considered inadvisable to proceed any further with the operation.

148 West Seventy-seventh Street.

Myoclonic Form of Epidemic Encephalitis.—Sicard and Kudelski describe a case of epidemic encephalitis with predominance of diaphragmo-abdominal myoclonus. It is characterized by pains and myoclonus most marked in the region of the diaphragm and abdomen. Lethargy is completely absent as are likewise ocular disturbances.—*Gazette des Hôpitaux.*

PROLONGED FEVER OF UNDETERMINED ORIGIN IN CHILDREN: REPORT OF CASES.

By DAVID GREENBERG, M.D.,

NEW YORK.

ADMITTING PHYSICIAN AND ASSISTANT IN PATHOLOGY, LEBANON HOSPITAL.

PEDIATRICS as a specialty has come into its own only in late years. Most children, however, are still being treated by the general practitioner or "family doctor." It is, therefore, within the realm of the general practitioner to discuss some morbid conditions which, while not peculiar to children, are relatively more common in children than they are in adults.

Nearly every physician of experience may possibly recall some instance when he was called upon to treat an infant or child who had fever, when he failed to discover the cause of the rise in the temperature, even after careful, repeated, and painstaking examination. Not a few of these cases develop no diagnostic symptoms or signs while under observation and the trained specialist and laboratory man are not able to solve the problem for us. The layman relative of the patient may or may not be satisfied with a ready-made diagnosis, such as grippe, congestion of lungs, stomach trouble, or the old malaria; but we cannot be satisfied with such diagnosis if we want to be honest with ourselves.

My experience with the cases I am reporting was such that I am prompted to make this report with the hope of stimulating further study along the lines of the causes of fever in children. Some of these cases herein reported were seen by some of our best consultants and no definite diagnosis was made.

Case I.—B. B., female child, 1 year old. Family history negative.

Previous History.—Normal birth, breast-fed up to seven months, mixed feeding up to tenth month. Weaned at ten months, put on a formula of top milk, Walker Gordon preparation. Did well up to present illness.

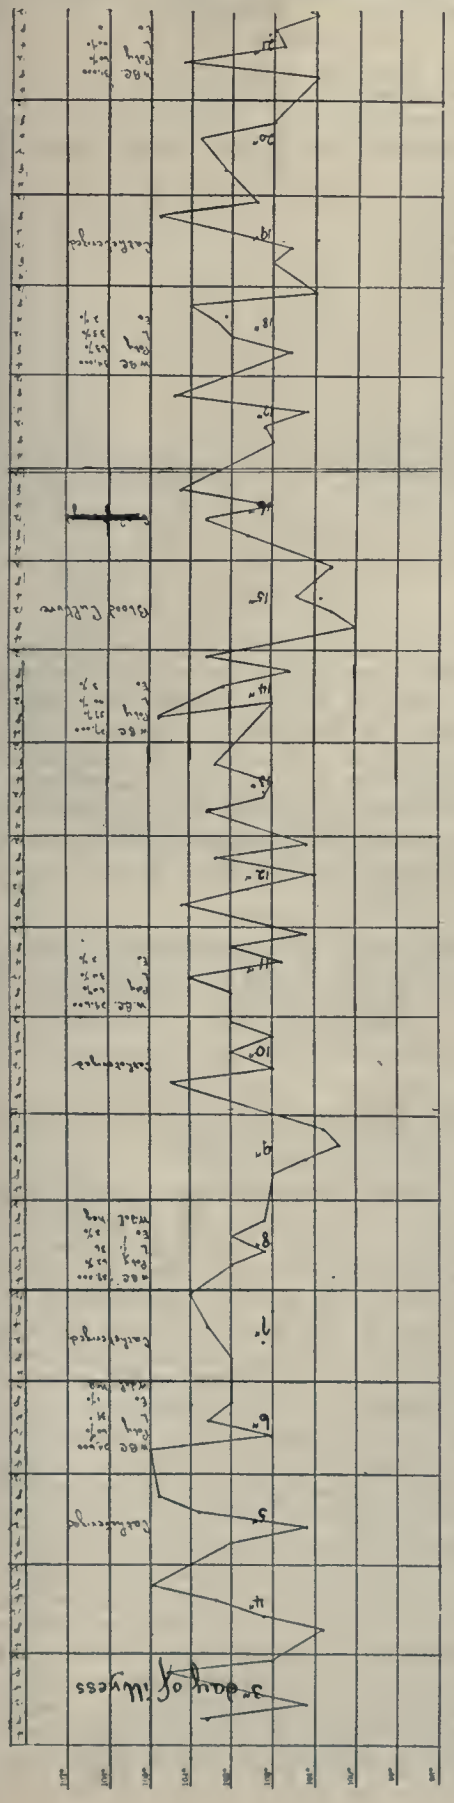
Present Illness.—Became ill suddenly with temperature of 102°, vomited twice at onset, was treated for influenza for two days before I saw her. On examination, I found a fairly well nourished child, not perceptibly prostrated, temperature 103.5°, fairly rapid pulse, respiration about 30, slight rigidity of neck, acid breath, skin and glands negative, as were the mucous membranes; no catarrhal symptoms. The rest of the examination was entirely negative except for a palpable liver, evidently not tender, urine negative, only a faint reaction to acetone.

In view of the acid breath, acetone in urine, palpable liver, and absence of other signs, I felt justified in making a diagnosis of acidosis. The subsequent clinical course, however, made me question my original diagnosis. While the acidosis responded to the alkaline treatment, the irregular remittent temperature continued for over a month and the liver remained rather large, at times almost reaching down to the umbilicus.

The course of the fever in this case is interesting. It would remit several times during the twenty-four hours, was often highest in the morning and after sleep. The child perspired rather freely. During this period the child never vomited again, had no diarrhea, passed considerable flatus, took its food, consisting of milk and cereals, with relish, never looked very sick, was playful at times, and slept fairly well.

The child was examined repeatedly by several specialists. No one was able to find anything to account for the temperature. They were all willing to assume an acidosis at the onset. The urine was examined fre-

quently and found normal. The ears were examined on several occasions and nothing abnormal could be seen. Several blood examinations were made and showed a high leucocytis throughout, 24,000 to 31,000 whites and 60 to 65 polymorphonuclears. A blood culture on the fifteenth day of the illness was negative. The Widal, which was taken on a number of occasions, was negative and a urine culture was negative.



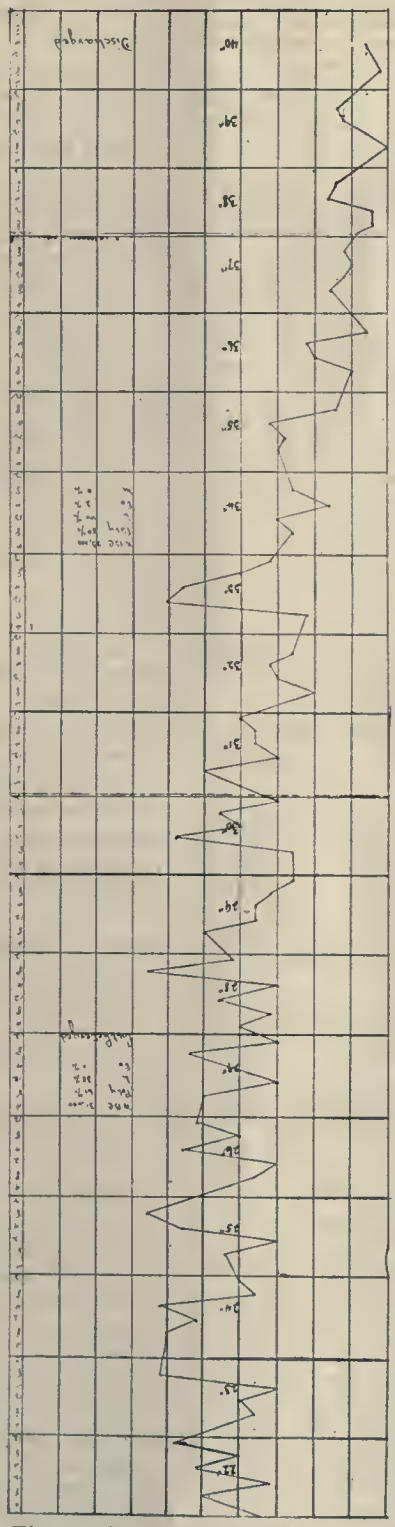


CHART 1.—Case I.

After about thirty-two days of fever the temperature came down by lysis, reaching normal about the thirty-fifth day. The liver continued large.

This child subsequently developed diminished breathing over the right lower lobe and also pus in the urine. This occurred some months later. A complete history and physical findings will be the subject of another communication.

CASE II.—Male child, 2½ years old, second child in family. Family history negative.

Previous History.—The child had measles eight months before onset of present illness.

Present Illness.—Became ill August 14, 1917, with fever, no vomiting. I saw him at night, temperature 105.5°, had twitching of extremities and left side of face, slightly rigid neck and exaggerated reflexes. Rest of examination entirely negative. On the child being given a mustard pack and high bicarbonate enema, the temperature came down to 102° and stayed there the entire following day. The temperature rose again to 105° the third day and was up every day between 104° and 105° for the following seventeen days.

During the whole febrile period the child gave no evidence of pain, did not vomit, had normal stool except at the onset, had no cough, was fairly prostrated at times and restless at other times. He had slight congestion of the throat and left ear drum for a few days and a palpable liver was noted on about the tenth day, which remained palpable throughout the illness. He also had a few suspicious areas on the chest, increased voice and slight dulness on about the twelfth day, which disappeared the following day.

The urine contained a faint trace of albumin at the onset and cleared up about the sixth day under alkalies. The blood showed a moderate leucocytosis 15,000 to 19,000 whites and 60 to 70 polymorphonuclears. The Widal was negative, one stool culture was negative both for typhoid and paratyphoid. Throat cultures were negative. The cerebrospinal fluid taken on the ninth day of illness came under slight pressure, otherwise negative.

CASE III.—Baby girl 7 months old; was a forceps case. Family history negative. Previous history negative; is receiving mixed feeding.

Present Illness.—Became ill December 9, 1917, with fever and vomiting. The temperature at the onset was 104.5° and remained thereabouts for fifteen days, having only slight remissions in the early afternoon. The physical examination was negative except for some distention of the abdomen and palpable spleen, which, however, is not uncommon in infants. In this case a diagnosis of influenza was made and for several days I strongly suspected the possibility of a pneumonia. Nothing developed, however, and the child remained ill for about two weeks, when

the temperature came down by crisis and remained normal.

The blood here too showed a leucocytosis 17,000 to 21,000 on three occasions. Polymorphynuclears ranged between 56 and 60. The urine obtained by catheterization was negative on several examinations.

Comment.—The possibilities in these cases are numerous. Some of those that were considered and eliminated are

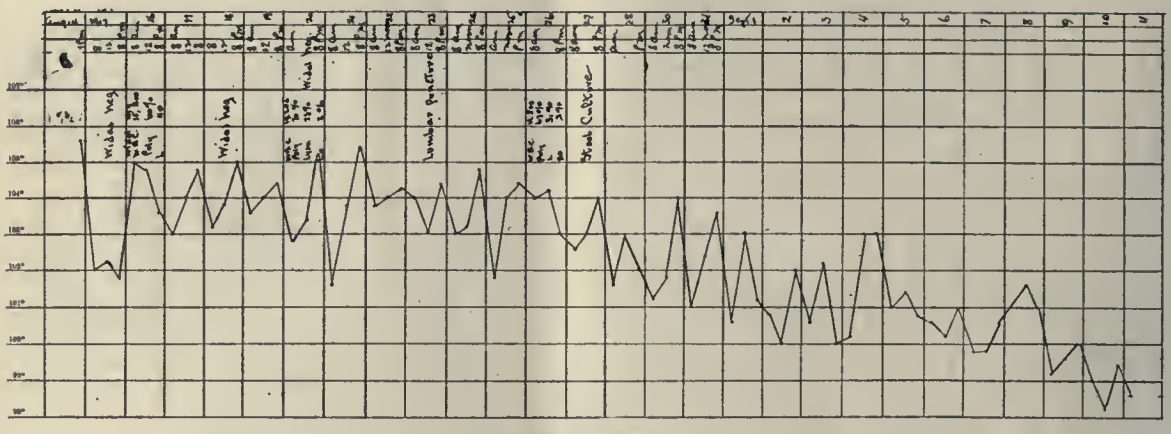

CHART 2.—Case II.

1. Typhoid Fever. The leukocytosis, the absence of rash, the negative widal, and the negative culture of the stool in Case II, rule it out.

2. Influenza. The leukocytosis and absence of catarrhal or respiratory symptoms or signs, are against this disease.

Pneumonia.—Is one justified in making a diagnosis of pneumonia on the temperature alone? In none of these cases were there any definite signs in the lungs. Unfortunately, all these cases were treated in their own homes and no *x*-rays were taken.

Pyelitis.—Negative urinary findings are against this. The temperature in Case I strongly suggested it, but no pus was ever found.

Sinusitis.—No nasal discharge, no throat involvement. It is possible, though, that with the more thorough examination, including *x*-ray of sinuses in chil-

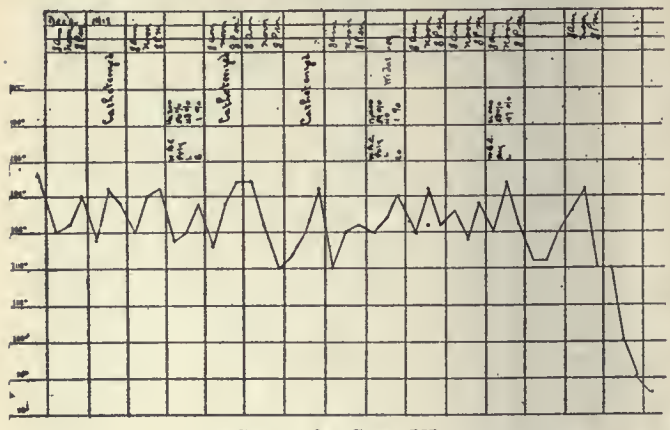

CHART 3.—Case III.

dren, some of these fevers may be cleared up.

Pneumococcus-peritonitis.—Was considered, especially in Case I. But there was no tenderness, no masses, no rigidity, no diarrhea or constipation.

Intestinal infection, which was the diagnosis made by one of the consultants in Case I, is not convincing. There was no gastric or persistent intestinal symptoms or signs, and the leucocytosis would speak against it also.

Septicemia.—This cannot be ruled out. Yet there was no discoverable portal of entry and at least one blood culture was negative.

It would appear that many febrile attacks in children cannot be properly classified as belonging to any clinical entity. It is possible that some of these are due to the ordinary bacteria which gain entrance into the body, and perhaps the blood stream, in an unrecognizable manner, without giving any local manifestations. Again, some yet unknown microorganism may be the causative factor.

It seems unscientific to call these attacks grippe, intestinal trouble, malaria, or even central pneumonia because we do not know what else to call them. We ought to be a little more critical and careful in our diagnosis and should not accept mere phrases. Perhaps with the help of the newer laboratory methods we may eventually clear up these unclassified infections and be able to form a better conception of these often puzzling cases.

1220 GRAND CONCOURSE.

DOES COMMUNITY RESPONSIBILITY END WHEN SANATORIUM TREATMENT HAS BEEN GIVEN?*

BY MAJOR R. C. KIRKWOOD, M.R.C., U.S.A.,

PRESCOTT, ARIZONA.

MEDICAL DIRECTOR, PINE LAWN SANATORIUM; FORMER CHIEF OF MEDICAL SERVICE, U. S. ARMY GENERAL HOSPITAL, FORT BAYARD, NEW MEXICO.

THE question which forms the subject of this talk is a pertinent one and one which should engage our serious attention. It presents a problem, a solution of which public welfare workers have all sought but without satisfactory results. Therefore in attempting to answer that question I feel like the proverbial high school graduate, who in his commencement day thesis solves some problem of political economy which the trained statesmen of the country have tried in vain to solve. However, I have some very definite ideas as to what we *can* do and will present these ideas as briefly as possible. The answer to the question forming the title of this talk is obviously *no*. Our responsibility most certainly does *not* end when we discharge the patient from the sanatorium. In our public institutions, where it is our aim to help the greatest possible number, patients are not retained under treatment so long as they are in private sanatoria and when discharged from the public institution the case is usually merely "improved," lesion "quiescent."

*Read before General Session, Miss. Valley Tuberculosis Conference, Des Moines, Iowa, Sept. 23, 1919.

Therefore there is still much to be done for this patient and in the past we have not been doing our duty by these patients. When they are discharged from the sanatorium they are just being started on the way to complete and lasting arrest of their diseases. They are rather in the position of one just graduated, they are just out of a training school in which they have been taught how to live to secure and retain a complete arrest of the disease. The sanatorium is, or ought to be, the great training school for the tuberculous, and if it is not it has failed in one of its most important functions. Major Watterson has just told us that 52 per cent. of the so-called "arrested" cases discharged from sanatoria "break down" again, often much worse than when they first fell victims to this disease. This indicates to my mind that there has been something wrong with our "follow up," not with the sanatorium, though the sanatorium has been blamed for this condition of affairs and many have wondered if sanatoria are worthwhile. Without proper "follow up" they are hardly worth while; with this proper supervision after discharge from treatment I am quite sure any doubt as to the place and value of the sanatorium in the tuberculosis program will be quickly dispelled. What then is our further duty to the patient after we have given him sanatorium treatment and returned him to his home? During his stay at the sanatorium he has been taught, or at least, should have been taught, how to live to secure and retain arrest of the disease. When he is returned to his home the source from which he was sent to the sanatorium should be notified and a public health nurse or other similar officer should visit the home and see to it his home conditions are not inimical to this end. She should see that the home is not overcrowded, particularly as regards sleeping quarters, that there are provisions for open air sleeping or its equivalent, that cleanliness prevails, that the home is equipped with proper plumbing, that it is properly lighted (not artificially in day time), and properly ventilated. She should assure herself that the patient will get proper rest and recreation, as indicated in the individual case, and proper quantity and quality of food, well prepared. The family should be taught the need for the changed manner of living on the part of the former sanatorium patient so that they will not make it impossible for the patient so to live, as is so often the case. In our community among the foreign element which predominates the Captain John Smith principle of "he who does not work shall not eat" seems to prevail. The members of the patient's family do not see the need for better food, rest, etc., and by their attitude cause the patient to give up the mode of life outlined for him. The patient should have it impressed upon him that he is *not* cured and that he can be only by strict adherence to the prescribed régime for a long period, likely several years. He should be taught that chest pains, loss of weight, ease of fatigue, a repeated rise of temperature to 99° or above, increased pulse rate and, more important, an unstable pulse, loss of appetite, digestive disturbances, etc., are danger signals which should bring him to "The Clinic" routinely, first every month, then every two months, every three months, and finally as he "carries on" without ill effect only twice a year. This in order to detect evidences of renewed activity early. His work should be chosen for him with his physical condition in mind, and if it is not thought advisable for him to return to his former occupation he should be trained for other work, which he can do. It should be seen to that the conditions under which he works are ideal, if in shop or factory that it is properly ventilated, supplied with an abundance of properly diffused daylight, with proper sanitary plumbing, etc. It should be seen to that his hours on duty are not too long, that he gets proper noonday nourishment and a sufficient amount of time off for rest and recreation. The general sanitary condition of his place of work should be the best possible. The ideal arrangement is, of course, the industrial and agricultural colonies now being advocated where patients are under direct supervision, their families under similar supervision, colonies with increasing amounts of work and lessening of the closeness of the supervision, the patient "graduating" from one to another as he proves his ability to do the work without ill effect. Such colonies, now being planned, will, I feel sure, soon be a reality and will help greatly to solve this important problem. In the meantime we must do the best we can with the means at our disposal. Personally I try to give discharged patients work at the sanatorium for a time before they return to their former industrial or agricultural pursuits and so I am enabled to keep them under supervision, see how much work they can do and above all "harden them up" before sending them out to compete with healthy workers. There is the big reason for the supposed failure of the sanatorium. Patients are placed at rest, fed up until they are fat and flabby and in this condition returned to active life without any preliminary "hardening" process. The natural result has been a "break down" under the strain. It is our duty to get them ready for work before we return them to their industrial or agricultural pursuits. "Healthwin," the St. Joseph County Tuberculosis Sanatorium, at South Bend, Ind., has recently started to provide or cause to be provided for discharged patients this proper "follow up" care. "Sunnyside," the Marion County (Indiana) Sanatorium, near Indianapolis, has for some time been rendering similar service. Replies to an inquiry sent out to many tuberculosis associations and sanatoria by Miss Gaskill, the director of Out-Patient and Social Service at "Sunnyside," indicate, however, that with but few exceptions such service is being rendered in a most indifferent manner or not at all, more frequently the latter. Only one institution in Wisconsin is doing any such work at present; the Chicago Tuberculosis Institute reports having just recently inaugurated such service in connection with Edward Sanatorium; Minnesota reports "no definite follow up work being done"; Cincinnati reports the system to be inadequate, and so on. But I shall not take up your time to analyze these reports. Suffice it is to say sufficient and efficient "follow up" work is not being done and without this our sanatoria will fall short of rendering their best service.

Summing up, then, we must educate the patient and his family in the need for proper living, see that the patient's housing and working conditions

are proper and that he is properly nourished, keep in touch with him by examinations at the clinics, and so on. This work is of importance in the conduct of a tuberculosis sanatorium—

1. "To the patient because of the close personal relationship established in his home by the nurse."

2. "To the family by advising other members of the family to be examined and encouraging them in carrying out a routine of personal hygiene."

3. "To the community by spreading knowledge of general hygiene."

4. "To the institution by establishing a better understanding of the service rendered by such an institution."

There is still much to be done for the patient after he is discharged from the sanatorium, it is the duty of the community to make it possible to render this further service to the patient and it is our duty to show the need for this work and secure the support of the community in carrying out this plan without which sanatoria will not give us the greatest possible returns and money expended for their maintenance will not be spent to best advantage. The responsibility of the community in the matter of care of the tuberculous does *not* end when sanatorium treatment has been given.

I am indebted to Miss Gaskill, Director of Out-Patient and Social Service at "Sunnyside," the Marion County (Indiana) Sanatorium, for data used in the preparation of this paper.

Medicolegal Notes.

Only Expert Testimony of Weight as to Proper Performance of Surgical Operation.—In an action for malpractice for negligently permitting the broken ends of the bone to overlap and remain in that condition in treating the fracture of the femur of the plaintiff's right leg about three inches above the knee, the plaintiff testified that the defendant used a bed slat as a splint, bound to the leg with strips of bed sheeting and adhesive plaster, with a weight consisting of a flatiron fastened to the leg by cords and adhesive plaster and hung over the end of the bed. The only expert testimony offered by the plaintiff was that of a physician who had lived in that community for fifty years and who qualified as a skilled physician and surgeon. He testified to the method he employed in reducing a fracture, that various kinds of splints were used, wooden splints that can be molded to the part, various kinds of fiber splints, pasteboard, and plaster parts and other forms; that these have to be changed repeatedly, depending upon indications. His direct examination showed nothing from which a jury would be justified in finding that the method adopted by the defendant was not proper. Nonexpert witnesses, it was held, can testify as to external appearances and manifest conditions observable by any one, but whether a surgical operation has been performed with a reasonable degree of skill, knowledge and care, and whether the patient was thereafter skilfully and properly treated are questions of science, to be established by the testimony of witnesses of special skill and experience, and not by testimony of those who are without special learning and skill as to such operations and practice. Here the only expert called to testify on behalf of the plaintiff was the one physician, who neither criticised nor condemned the methods employed by the defendant in the treatment of the plaintiff's injury. It is true that the physician is bound to possess and exercise that degree of skill which is ordinarily possessed by physicians in practice, but where his errors are those of judgment only, if he keeps within recognized and approved methods, he will not be liable for their consequences. Negligence of a physician or surgeon cannot be presumed from the mere failure to obtain the best results from an operation or treatment, and where, as in this case, there is no proof of a want of skill or care on the part of the defendant, it is held error to set aside a judgment in his favor and grant a new trial. In regard to its holding as to nonexpert evidence, the court said that "a moment's reflection upon the circumstances and emergencies under which physicians are frequently called upon to act will demonstrate some of the disastrous results that would follow if the law permitted them to be mulcted in damages upon testimony as to the character of their professional services given by nonexpert witnesses. If such were the law, physicians and surgeons might as well be held to guarantee a successful cure or a successful operation in each instance." The court quoted from the opinion of the Supreme Court of Minnesota in Staloch v. Holm, 100 Minn. 276, 283, 111 N. W 264, 267, as follows: "Physicians and surgeons deal with progressive inductive science. On two historic occasions the greatest surgeons in our country met in conference to decide whether or not they should operate upon the person of a President of the United States. Their conclusion was the final human judgment. They were not responsible in law, either human or divine, for the ultimate decree of nature. The same tragedy is enacted in a less conspicuous way every day in every part of the country. The same principles of justice apply. Shall it be held that in such cases, where there is a fundamental difference between physicians as to what conclusion their science applied to knowable facts would lead to, then what they with their knowledge, training, and experience are unable to decide, and what, in the nature of human limitations, is not susceptible of certain determination, shall be autocratically adjudged by twelve men in a box, or by one man on the bench, or by a larger number in an appellate court, none of whom are likely to have the fitness or capacity to deal with more than the elements of the controversy? All the court can properly do if an action for negligence should be brought in such a case would be to direct a verdict for the physician."—Paulich v. Nipple, Kansas Supreme Court, 180 Pac. 771.

Medical Expert's Answer as to Permanence of Injury.—In an action for an injury to a woman caused by a collision at a crossing between the defendant's interurban car and a buggy in which the plaintiff was riding, a motion was held properly refused to strike out the words "it might" from the answer of a medical witness to a question as to whether the injury would permanently affect the plaintiff's nervous system. The basis of the motion was that the answer was speculative. It is held that an expert may answer such a question. One not specially learned cannot know, or intelligently answer, as to such a matter. One specially learned cannot, in many cases, be positive, and can only express a general conclusion in indefinite terms. The doctor was the one to know how definite the answer could truthfully be made. Such an answer by one so skillful is not speculative.—Terre Haute, I. & E. Traction Co. v. Stevenson, Indiana Supreme Court, 123 N. E. 785.

Authority of Health Officers to Make Regulations.—The New York Appellate Division holds that neither under the charter of the city of Rochester or the health ordinance enacted thereunder, nor under chapter 559 of the Laws of 1913 adopting the Public Health Law providing for a public health council, or the Sanitary Code enacted thereunder, can the health officer and commissioner of public safety of the city of Rochester prescribe general regulations, such as that an applicant for a license to sell milk must submit to a blood test for the purpose of determining whether or not he had ever had typhoid fever or was a carrier of typhoid germs. The court says that the scheme of all this legislation is evidently to require the concerted action and judgment of more than one individual as a prerequisite to general regulatory measures, leaving in the commissioner and the health officer a discretion only in the manner of applying in detail those general regulations. The commissioner and the health officer are administrative officials. They have no power to legislate, though they may determine facts and conditions which make applicable the general regulations, and may even prescribe regulations for carrying into effect the general enactments of the appropriate legislative bodies.—People v. Hamilton, 177 N. Y. Supp. 222.

MEDICAL RECORD.

THE SYMPTOMS AND DIFFERENTIAL DIAGNOSIS OF EPIGASTRIC HERNIA AND GASTRIC ULCER.

PAINLESS epigastric hernia is probably a more frequent condition than is generally suspected, but among the symptoms to which this type of rupture may give rise are pain and vomiting. Unquestionably, in corpulent subjects, it may be difficult to detect an epigastric hernia, but if the subject is placed in the Trendelenburg position and made to cough the lesion can usually be discovered. The preponderant symptom in both epigastric hernia and gastric ulcer is pain. A hernia will occasionally provoke very sharp pain confined to the epigastric region or it may give rise to a dragging sensation or to one of weight, occurring when certain movements are made. The pain does not always remain confined to the epigastrium as it can assume the girdle type, being frequently mistaken for intercostal neuralgia, and although the pain may not be provoked by certain positions of the patient, it is at least increased by them.

The pain of gastric ulcer offers some distinctive characters and varies greatly in intensity according to the case. In some patients a feeling of weight and dragging only is complained of, but on close questioning the pain in ulcer will be found to be most frequently to the right of the median line, though sometimes to the left. The pain extends to the right toward the back or the arm, the dorsal point of pain in this process being between the shoulder blades. The pain provoked in epigastric hernia by movement occurs at any time of the day; not so with gastric ulcer, which is directly related to the state of repletion of the stomach, although a full stomach will sometimes cause pain in cases of gastric hernia from traction on the omental contents of the sac. But pain occurring at the same hour each day should lead to the search for other symptoms of ulcer, either gastric or duodenal.

The second very important and frequent symptom of both processes is vomiting. In epigastric hernia it may be so severe as to compromise the patient's health. The vomitus is bilious, mucous, and influenced by certain positions assumed by the patient. The vomiting occurs soon after eating but never when the patient is lying down. Vomiting in ulcer occurs at times corresponding to periods of gastric intolerance, so that feeding becomes impossible, and is accompanied by painful paroxysms. Relief from the pain takes place when vomiting occurs. In other cases the vomitus assumes the nature of that found in gastric retention, the ulcer having produced a certain degree of stenosis. In this case it is more copious and less frequent. Some cases have been reported in which an epigastric hernia has given rise to hematemesis, but this is uncommon and should lead one to suspect a gastric lesion. The stomach is rarely involved in the hernia so that direct trauma of the gastric wall resulting in hemorrhage is out of the question. Circulatory disturbances due to thromboses of the omental vessels, the omentum being caught in the sac, will give rise to unimportant hemorrhage, if any at all. Palpitation of the epigastric region will give certain indications, especially if the pain complained of is superficial or deep seated. If hernia is the cause, the maximum pain will be found on pressure over the hernial ring or near it, while if a gastric ulcer is the cause only deep palpating will give rise to pain, usually to the right of the median line. The recti muscles will also be rigid.

Besides these subjective symptoms the patient will invariably present functional digestive disturbances. The gastric chemism shows that there is often a hyperchlorhydria alone associated with gastric hypersecretion. Some maintain that this is a reflex hyperchlorhydria, the starting point of the excitation being seated in the hernia and by the anastomosis of the intercostal nerves with the splanchnics stimulating the glandular system of the gastric mucosa—a plausible theory which may explain many cases of simple hyperchlorhydria. It is probable that this condition alone cannot give rise to the symptoms complained of by the patient and many cases of Reichmann's disease are known to have had prepyloric ulcers, so that gastric chemism can hardly give a precise diagnostic indication. More important is the search for blood in the stools, which should never be neglected. Some observers maintain that radioscopy is more useful than radiography in making a diagnosis of gastric ulcer, but this is probably a matter of temperament on the observer's part.

INTERNAL SECRETIONS AND VITAMINES.

PROGRESS is being made in the study of the manner in which the body is developed, which means that knowledge of the endocrine glands and internal secretions is advancing. Up to the present time their functions in the adult have been chiefly considered, the defective, perverted or excessive action of the thyroid gland, the defective action of the adrenalin glands, disease of the pituitary gland, and a long list of disorders owing to the disturbance of the due coordination of these glands. Important and instructive as these studies are, they sink into relative insignificance when compared to discoveries

relating to the functions of the ductless glands in development. For example, it has long been a matter of common knowledge that cretinism, distinguished by dwarfish idiocy, is the result of thyroid failure in childhood, and other discoveries in the same direction are in the making. The endocrine glands and the proper coordination of these glands, frequently termed the "endocrine balance," are essential to the development, seeing that they are in a manner of speaking the directors. Minute specks of glandular tissue must be carefully studied from this aspect. It is not enough to observe closely those glands which have no ducts and apparently do not secrete or rather secrete only internally.

The better known glands, with ducts and secretions, may also produce internal secretions. Of great importance from the age of puberty onwards are the internal secretions of both sexes of the glands of reproduction. These are essentially internal secretions, but they influence development to such an extent that the boy cannot become a man nor the girl a woman without their pervasive and dominating influence. Every one of these internal secretions is a marvel of chemical complexity, and there is no need for wonder that the "endocrine balance" is disturbed so frequently.

These discoveries appear so wonderful that the question may be asked whether we are ever likely to have any means of control over biochemical reactions of such intricacy. Recent discoveries regarding vitamines or accessory food factors are commencing to point out the way. Researches with regard to beriberi and rickets have shown us that two of the vitamine groups are necessary for development. Is there then any relation between these and internal secretions? Dr. Gowland Hopkins has suggested that we may not only have to deal with two distinct and independent factors of growth, internal or endogenous, and external or dietetic respectively, but that rather the action of the external or dietetic factors, the vitamines, is to simulate or activate the internal or endogenous ones. Briefly, according to this theory, the vitamines act by stimulating the endocrine glands and regulating the endocrine balance.

All this offers a fruitful and splendid field for research, and it may be said is quite in line with the trend of medicine of to-day—preventive. Because if we can find how to influence the development of the young we shall be able to prevent the occurrence of many diseases.

In the future it is probable—nay, it appears almost certain, that physiology and pathology must be taught on a different basis. In the future the study of development and the prevention of the factors which turn it into a wrong direction or arrest it may be considered fundamental in the teaching of physiology and pathology.

CARE OF THE INSANE IN SYRIA.

FROM the twentieth report (for 1918 and 1919) of Lebanon Hospital for the Insane at Asfuriyeh, near Beyrout, Syria, it is interesting to note that while all other institutions were closed during the war, this one for the care of the insane, those whom the Moslems look upon as afflicted by the hand of God, remained open during the entire time. This was made possible, according to the director, Dr. Watson Smith, because of the peculiar nature of the work. For while the Moslems will do nothing themselves for the insane, they will not interfere with the work of others in behalf of these unfortunates. The Turks shut down every other foreign institution, but did not interfere with this one; in fact they showed a particular liking for it, and when, soon after Turkey entered the war, they heard that the hospital was having difficulty in obtaining wheat, Djemel Pasha, governor of Syria, one of the Turks active in the war, sent a hundred sacks of flour. In time, however, through the exigencies of war, particularly trying in that part of the world, the difficulties of obtaining food were so great that actual starvation threatened the inmates of the hospital, while thousands of the civil population were dying for lack of food.

When, in the midst of this tragic situation, the British troups came to Beyrout, tired and worn from rapid military operations, and invading troops at that, they did not take long, according to Dr. Smith, to provide their motor wagons to bring wheat to the starving. The Germans, on the other hand, although actually on the ground and in control for months, and seeing the frightful misery about, could not spare their motor wagons to carry wheat, although they were constantly running to Beyrout to transport silk, passengers, or anything for profit. On one occasion, we are told, when camel or rail transport were quite impossible the hospital was obliged to pay to the German military authorities the sum of one hundred and sixteen Turkish pounds for the transport of two tons of wheat from Rayak in motor wagons which were going to Beyrout empty in any case. When the Germans and Turks were escaping from Beyrout on the advance of the British troups, the Turks gave what supplies they had (it was impossible to transport them) to the poor about, while the Germans threw their supplies into the sea.

In the face of such difficulties this worthy institution kept its doors open for the reception and care of a most pathetic element of the Syrian population. One can but hope and believe, after reading this report, that the appeal for funds with which to make this institution an up-to-date hospital for the care of the insane will be generously met.

PULMONARY MANIFESTATIONS OF MALARIA.

THE question as to whether a pure malarial infection can produce the symptoms and physical signs of bronchitis, pulmonary congestion, and consolidation is a vexed one. Some authorities say yes and others dispute the point. In the *Quarterly Journal of Medicine* for October, 1919, Dr. A. W. Falcolner records his experiences in this direction in Macedonia during 1917 and refers to the work

carried out by Anderson and himself in 1916. He classifies the pulmonary manifestations which he observed into the following groups: (1) Bronchitic. (2) Pleuropulmonary congestion with more or less definite evidence of consolidation. (3) Massive collapse of the lung. (4) Concurrent malaria and pneumonia. (5) Pneumonia occurring in chronic malaria without evidence of active malaria. (6) Pleurisy, either dry or with serous or hemorrhagic effusion. Of these he found the bronchitic type the most frequent and states that its most characteristic feature is the way in which the stethoscopic signs vary within a few hours and flit from one position of the lung to the other. The aggravation of symptoms during pyrexia is noted and the sputum generally profuse, is fairly characteristic. The physical signs disappear with remarkable rapidity when quinine is exhibited in adequate amount. This, together with the character of the physical signs, points to the condition being the direct result of the malarial process. Pleuropulmonary congestion with evidence of consolidation is not uncommon. The physical signs are those of pneumonia but general symptoms of pneumonia are lacking or very slight. The physical signs vary with great rapidity. There is no leucocytosis and the condition is amenable to quinine. Concurrent malaria and pneumonia are not rare and the pneumococcus has often been recovered from the blood in such cases. Once the lung symptoms are definite, quinine treatment does not influence the condition. Dry pleurisy is not common, and wet pleurisy is rare. The conclusions that Falcolner reaches are that, although malaria is frequently complicated by pneumococcal infection, numerous cases occur in which there are notable changes in the lungs without any evidence of superadded infection. These may present the physical signs of bronchitis, pulmonary congestion with more or less definite evidence of consolidation, or massive collapse of the lung. In many cases the symptoms at first are almost entirely pulmonary and the malaria infection may be entirely overlooked. Its recognition at the earliest possible moment is important, as untreated with quinine there is a great liability for the lung to become secondarily infected, with the development of true inflammatory changes.

Mobilization of Fractures of the Mandible.

One of the surgical lessons of the war, learned largely through the labors and teaching of Professor Willems of Belgium and Mr. Dowden and others of England, is the undesirability of immobilization in the treatment of broken bones, not only gunshot fractures but those occurring in civil life as well. Mr. William Guy, writing in the *Edinburgh Medical Journal*, March, 1920, applies this principle of mobilization to the treatment of fractures of the mandible. He is of the opinion that there is no fracture on which there has descended with greater malignity what his friend Mr. Dowden has called "the curse of immobilization." Guy quotes from Lucas Championnière's classic "Traitement des Fractures par le Massage" in support of the view that prolonged immobilization is usually contraindicated in the treatment of fracture of the mandible. Guy argues that the aim of treatment should be the re-establishment of function at the earliest possible moment. It is of importance that the fracture should at the termination of treatment be united; it is of still greater importance that the patient should have a lower jaw which is movable, which, in short, he can use. Immobilization in treatment in many instances defeats the attainment of this result. The advocates of immobilization contend that this is necessary to prevent displacement of the fragments by muscular action, and to ignore the action of the muscles as a distorting agent is regarded by many surgeons as a horrible heresy. Guy declares that if this be so, he is another horrible heretic, as he prefers to believe that the main thing is to encourage and assist the patient to correct displacement. In this the muscles directed by the will are the effective factors, and the correct position once obtained is, provided movement has been permitted from the first, generally maintained without assistance. The writer describes at some length the technique of the methods for treating different kinds of fractures of the mandible. He even goes so far as to believe with his mentor, Lucas Championnière, that the dictum that movement is necessary for the successful treatment of fractures is even more applicable to compound than to simple fractures, and acting on these principles he has treated over four hundred fractures of the mandible caused by gunshot wounds of every degree of severity. In the result he is confirmed in his conviction that "le mouvement c'est la vie."

Retrospect of Influenza.

Hergueta makes some original contributions to the history of influenza in Spain. He mentions the outbreaks in 1889 and 1898, both of which began in November. At first cases were simple, but after the sixth week the disease began to be severe. Figures are given of the mortality of grippe from November, 1914, to January, 1920, by years. During the first year the deaths totaled 2,499; during the last year 4,789. The epidemics abated in January in both 1889 and 1919, which appears to show the influence of weather conditions on the severe type of disease. The author whose study appears in *El Siglo Medico* for March 20, 1920, lxvii, 3458, states that the progress of epidemic influenza is always from North to South and from East to West. Of ninety-two epidemics the vast majority ran from November to January. The disease is a universal depressant of function and of resistance to infection. Great virulence in the germ attack may be seen in the robust, while weakening of the resistance to disease is seen in the lighting up of tuberculosis and other diseases. In those carried off in the first day or two, we may often see a special predisposition. The author cites several such patients in whom the sympathetic nervous system was compromised—false angina pectoris, etc.—who quickly succumbed. He is unable to offer any explanation as to why this should be so.

The Pilomotor Reflex.

According to Thomas in *La Médecine* for February, 1920, i, 5, gooseflesh is an index of the state of the sympathetic nervous system. The phenom-

enon may be produced locally or at a distance by irritating the skin. Some parts of the skin are more reflexogenic than others and this may vary in different subjects. Psycho-affective states may elicit the phenomenon. The reflex may become exhausted by frequent repetition of the stimulus. Reflexes may be unilateral if the excitation is unilateral. Under the head of pilomotor reflex the author would include the scrotal and nipple reflexes. In eliciting this reflex one has one of two objects. First, to test the centripetal paths and, second, to test the centrifugal paths of the arc. The author has tested the reflex in many serious wounds of the medulla. He found that the pilomotor centers of the superior extremities were seated in the fourth and seventh dorsal segments, while those for the lower extremities were seated in the ninth and twelfth dorsal segments, and the first and perhaps the second lumbar segments. Persistent gooseflesh without efficient cause indicates a heightened pilomotor tonus. In eliciting the reflex one may use a number of stimuli, as pinching the neck or the trapezius muscle or the application of cold to the thorax or abdomen. Many facts have been collated about the reflex, but as yet they do not seem to have been formulated and the author does not commit himself to the laying down of laws of action.

News of the Week.

Officers of the American Medical Association.

(By Telegraph to the Medical Record.)

At the meeting of the House of Delegates on Thursday afternoon, the following officers were elected:

President, Hubert Work, Pueblo, Colo.;

First Vice-President, Isadore Dyer, New Orleans, La.;

Secretary, Alexander R. Craig, Chicago, Ill.;

Treasurer, William Allen Pusey, Chicago, Ill.;

Speaker of the House of Delegates, Dwight H. Murray, Syracuse, N. Y.;

Vice-Speaker of the House of Delegates, Frederick Cook Warnshuis, Grand Rapids, Mich.;

Trustees, Charles H. Richardson, Washington, D. C.; Wilbur T. Sarles, Sparta, Wis.; Walter T. Williamson, Portland, Ore.;

Member of the Judicial Council, Ira Carleton Chase, Ft. Worth, Texas, for the term of five years;

Member of the Council on Health and Public Instruction, Milton Board, Louisville, Ky., for the term of five years;

Member of the Council on Medical Education and Hospitals, Ray Lyman Wilbur, Stanford University, California, for the term of five years;

Member of the Council on Scientific Assembly, J. Shelton Horsley, Richmond, Va., for five years; Franklin P. Gengenbach, Denver, Colo., for four years; John Edward Lane, New Haven, Conn., for one year.

The next annual session, in 1921, will be held in Boston.

Jacobi Memorial Meeting.—The New York Academy of Medicine will hold a memorial meeting in honor of the late Dr. Abraham Jacobi on the ninetieth anniversary of his birth, May 6, at 8.30 p.m. A bas-relief of Dr. Jacobi will be presented by George McAneny, Esq. It will be accepted by the President of the Academy, Dr. George David Stewart. An oration will be delivered by Dr. George Vincent of the Rockefeller Foundation.

Health Officers to Meet.—The first conference of Ohio health commissioners with the State Department of Health will be held in Columbus, May 12, 13, and 14. Under the new health law it is the duty of every board of health, whether of a city or general district, to appoint the health commissioner as a delegate to the conference.

Typhus Fever.—It is announced from Belgrade that sanitary conditions in the Balkan region are daily assuming more serious aspects, and there is grave danger from the spread of typhus in many localities. Seven thousand Russian refugees have arrived there, and are under the observation and care of the American Red Cross. The U. S. A. Transport *Pocahontas* arrived recently in this port from Dantzig with 1,626 Polish soldiers, among whom were two cases of typhus fever. The soldiers and 150 civilian passengers were sent to Hoffman and Swinburne Islands for observation.

State Section of the American College of Surgeons.—The Montana section of the Fellows of the American College of Surgeons was recently organized in Butte with the assistance of Dr. Franklin H. Martin, national secretary of the organization. Decentralization of the organization and the establishment of State sections that will permit the members of the college to attend the annual meetings in their own territory is stated to be the object of forming State branches of the College.

Public Health and Prohibition.—Prohibition is increasing hospital efficiency and promoting economy in the treatment of hospital cases, according to Frederick D. Green, secretary of the United Hospital Fund of New York City.

The most significant figures quoted by Mr. Green were supplied by the City of New York Board of Ambulance Service under which the city is districted into ambulance zones. This board keeps a record of all calls in these zones. The following figures, giving the number of ambulance calls due to intoxication and alcoholism for the entire city were supplied by James L. Murray, Examiner of the Board:

January, 1919 (no prohibition)	412
February, 1919 (no prohibition)	364
January, 1920 (prohibition half month)	307
February, 1920 (prohibition entire month)	133

Mr. Murray called attention to the fact that Bellevue Hospital, whose services along alcoholic lines were formerly higher than any other hospital, showed, during the first two months under prohibition, the following reduction in ambulance calls for alcoholics:

January, 1919 (no prohibition)	136
February, 1919 (no prohibition)	92
January, 1920 (prohibition half month)	21
February, 1920 (prohibition entire month)	10

The New York Hospital, with the largest am-

bulance service of any private institution in the city, shows the following reduction in calls for alcoholic patients:

January, 1919 (no prohibition) 53
February, 1919 (no prohibition) 47
January, 1920 (prohibition half month) ... 28
February, 1920 (prohibition entire month) 14

There were proportionate decreases in ambulance statistics for Flower Hospital, Knickerbocker Hospital, Lincoln Hospital, and other New York City institutions.

Vacancies in Civil Service Positions Open to Physicians.—The Civil Service Commission of the State of New York announces examinations to be held May 15, for appointments to fill the following positions:

Sanitary Supervisor, State Department of Health. $3500. Age limits 21 to 50 years. Candidates must be physicians and graduates of recognized schools of medicine. They shall (*a*) have served as a health officer of a city, town or village having a population of not less 5,000 persons for a period of at least four years; or (*b*) shall have received instruction approved by the Public Health Council, or a duly authorized committee thereof, in sanitary science, including five hours of instruction per week during the school year in an educational institution, and shall have had at least two years of experience in public health work; or (*c*) shall have received a degree, certificate, or diploma in public health granted after the completion of a course approved by the Public Health Council, in an educational institution, and at least one year of practical experience in public health work; or (*d*) shall have submitted proof satisfactory to the Public Health Council, or a duly authorized committee thereof, that they have actually engaged in public health work of such a character as shall qualify them for the duties of the position. Appointees will not be allowed to engage in the regular practice of medicine or in any other regular occupation or business which will interfere with the full discharge of their duties. Open to both residents and non-residents.

Epidemiologist, State Department of Health. $3500 to $4000. Age limits 21 to 50 years. Candidates must be physicians and graduates of recognized schools of medicine. They must submit evidence satisfactory to the Public Health Council, or a duly authorized committee thereof, that they have had (1) not less than three years of experience in public health work which relates to the cause, prevention, and control of communicable diseases and actual experience in dealing with such diseases; (2) a practical knowledge of vital statistics, and the interpretation of figures relating to morbidity and mortality rates; (3) actual experience in the making of sanitary surveys in cities and rural districts, and (4) a working knowledge of bacteriological technique, which shall include the various methods of making specimens for submission to the laboratory, including lumbar puncture, blood cultures, and throat cultures. Open to both residents and non-residents.

Pathologist, Craig Colony for Epileptics, Sonyea, N. Y. Salary $2500 a year with maintenance. Candidates must be trained and experienced along the following lines, so that not only may they conduct work in these various branches, but direct that of others associated with them; neuropathology, general pathology, performance of autopsies, bacteriology, serology, working knowledge of the technique of various blood examinations and tests, including Wassermann and similar tests, uranalysis, making of vaccines, etc. They will be rated on education, training, experience, and personal qualifications. They may be required to make a written statement of their conception of the duties of the position. Inquiry may be made as to their character and ability and all statements of experience are subject to verification. An interview may be required.

Director, Division of Communicable Diseases, State Department of Health. $4000 to $4500. Age limits 21 to 50 years. Candidates must be physicians and graduates of recognized schools of medicine. They must submit evidence satisfactory to the Public Health Council, or to a duly authorized Committee thereof, that they have had not less than five years of experience in those phases of public health work which relate to the administration, cause, prevention and control of communicable diseases. Open to both residents and non-residents.

Assistant Bacteriologist, State Department of Health. $2000 to $2500. Age limits 25 to 45 years. Candidates should have a collegiate education or its equivalent; a general knowledge of the principles of physics and chemistry; and should possess a thorough knowledge of the principles of bacteriology, infection and immunity. They should have considerable practical experience in the bacteriologic and serologic diagnosis of infectious disease, and in the preparation and standardization of anti toxins, serums, and vaccines. Open to both residents and non-residents and to both citizens and non-citizens.

Application should be sent to the State Civil Service Commission, Albany, N. Y.

Medical Society Elections.—The Hartford (Conn.) County Medical Society, at its annual meeting held April 6, elected the following officers for the ensuing year: *President*, Dr. E. A. Wells, of Hartford; *Vice-President*, Dr. T. G. Alcorn, Thompsonville; *Secretary-Treasurer*, Dr. C. B. Brainard, Hartford.

The Massachusetts Homeopathic Medical Society, at its annual meeting held at Boston, April 14, elected the following officers for the ensuing year: *President*, Dr. George N. Lapham, of Rutland; *Vice-Presidents*, Dr. Charles T. Howard, of Boston, and Dr. Edgar A. Fisher, of Worcester; *Recording Secretary*, Dr. Nathan H. Garrick, of Boston; *Corresponding Secretary*, Dr. Benjamin I. Loring, of Watertown; *Treasurer*, Dr. Thomas M. Strong, of Boston; *Chairman of Censors*, Dr. Harry J. Lee, of Boston.

The South Carolina Medical Association, at its seventy-second annual meeting, held in Greenville, S. C., April 20-21, 1920, elected the following officers for the ensuing year: *President*, Dr. W. P. Timmerman, Batesburg; *First Vice-President*, Dr. J. M. Walker, York; *Second Vice-President*, Dr. W. A. Boyd, Columbia; *Third Vice-President*, Dr. W. W. Fennell, Rock Hill; *Secretary-Treasurer*, Dr. E. A. Hines, Seneca.

Obituary Notes.—Dr. Wallace Harlow Deane, of Springfield, Mass., died of pneumonia on April 10, at the age of sixty-seven. He was graduated from Yale University School of Medicine in 1877, and had practised in Springfield for forty years.

Dr. EDWARD J. CONNEL of New York City died of pneumonia April 11 at the age of 44. He was graduated from Cornell University Medical College in 1899, specializing in ophthalmology and otolaryngology.

Dr. JULIUS JEROME GOLDSTEIN of New York City died April 14 at the age of 36. He was graduated from University and Bellevue Medical College in 1909 and devoted his attention largely to tuberculosis.

Obituary.

JOHN W. S. GOULEY, M. D., NEW YORK.

Dr. J. W. S. GOULEY of this city died on Monday last at the home of his daughter in Brooklyn. He was born in New Orleans of French parentage on March 11, 1832. He was graduated in medicine from the New York College of Physicians and Surgeons in 1853, and after serving a year as interne in Bellevue Hospital, began practice in this city, devoting special attention to general and genito-urinary surgery. During the Civil War, from 1861 to 1864, he served as assistant surgeon in the United States Army. He was demonstrator of anatomy and instructor in histology and operative surgery in the Medical Department of the University of New York from 1859 to 1866, and professor of clinical surgery and genito-urinary diseases in the same institution from 1866 to 1871, and of genito-urinary surgery from 1876 to the date of his retirement from practice. He was surgeon to Bellevue and St. Vincent's Hospitals and held numerous other appointments during his long professional career. During the 70's and early 80's he made many valuable contributions to medical literature, chiefly on urological subjects.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, April 9, 1920.

Medical Practice in Dublin.—As may be imagined the terrible social and political conditions in Ireland have introduced a good deal of disorder into medical practice. Much credit therefore is due to Irish practitioners for the lack of serious consequences that have followed the many obstacles and difficulties they have encountered on every side. In ordinary times in many districts of Ireland medical practice is carried on under many and grave disabilities of undermanning, long journeys, and meager pay. The revolutionary times which now exist have naturally emphasized these disabilities, but scarcely to the extent which might have been anticipated. In a city like Dublin, however, the increased gravity of the situation is obvious. The medical man, so to speak, carries his life in his hands. Between the hours of midnight and five in the morning medical men are granted special permits, as also are nurses and those engaged in certain other legitimate business, to be abroad during prohibited hours, but it is needless to say that permission to be out and about by no means insures safety. The hesitation of a doctor, or the stupidity of an armed employee may bring about a tragedy at any moment. But over and above the dangers involved in the night work of a medical man there remains a tremendous amount of inconvenience, the result of the existing abnormal conditions of medical practice. Calls to attend are not received, sometimes because messengers refuse to carry out their functions or because in haste to discharge them they omit to obtain the necessary permits and are detained by the police authorities. The telephone service is inefficient and dilatory to an incredible degree, and it is absolutely impossible to procure special drugs or, in fact, any pharmaceutical material with the promptness which is so frequently essential to their remedial or curative employment. It says much for the courage and coolheadedness of the Dublin medical practitioners that under such critical and dangerous conditions they have continued their night services, on the whole, with success.

Tuberculosis Settlements.—The Ministry of Health have appointed Colonel Nathan Paw, the well-known Liverpool authority on tuberculosis, and Dr. Varrier Jones, tthe head of the Papworth tuberculosis colony, to visit various likely localities with a view to the establishment of village settlements for tuberculous ex-service men. This is in connection with the contemplated scheme for sanatoriums, to which reference has been made in previous letters.

Measuring Emotions.—Research as to many of the phenomena connected with the nervous system is proceeding apace. Some of the results of experiments in this direction are well deserving of attention as they possess a practical application. By means of the galvanometer, for instance, under the supervision of Professor Waller of South Kensington, it has been found that "large and sudden" electrical responses which are independent of any muscular movement, accompany a great many of the shocks and alarms of life. In the first series of experiments strong and disagreeable stimuli were used, that is, an unexpected loud sound, an unexpected burn, a disagreeable pungent smell, a painful thought. It was found that while muscular movement of any sort might be absent marked electrical reactions occurred. It was found likewise that the most effective ideas were such as were accompanied by disagreeable or painful emotion and that the threat of a burn was often more effective in altering electrical relations than the burn itself. Lighting a match might give a larger effect than the application of a match to the free hand. The apprehension of a bad smell which had just been experienced proved to be particularly effective. The expected prick of a needle produced in some cases more effect than an unexpected prick. The conclusion was drawn that different subjects react differently to different stimuli, and the same subject in different states of health and at different times of day react differently to identical stimulation. It will be observed that this kind of work amounts to a measurement of emotion in terms of electrical phenomena. It may later be possible to state to how great extent the stress and strain of modern life is caused by noise and other stimuli, a question of very great importance at the present time when energy has had to be expended in most prodigal fashion.

Cost of War Pensions.—According to the Ap-

propriation Account of the Ministry of Pensions the gross expenditure of the department in 1918-19 amounted to £46,563,831 against £23,152,123 in the previous year. Some of the principal items under the head of pensions and gratuities were: disabled naval officers, £73,706, disabled army officers, £623,570, treatment of disabled officers, nurses, and men, £4,587,753, training of disabled officers, nurses, men, and widows, £791,-254, provision of artificial appliances, £341,623. Owing to rapidity of demobilization and the large number of men who put forward claims to pensions on account of disability it was considered by the military authorities to be impracticable to carry out the normal procedure of bringing such men before medical boards, and provisional examination by a medical officer was substituted. In the exceptional circumstances the Auditor-General raised no objection to the grant of temporary pensions, and examination by a medical board takes place before renewal. In addition to agreements on a capitation basis with various institutions for the treatment of discharged and disabled officers and men, proposals for the provision of hospital accommodation under ministry control were placed before the treasury in 1918. Subject to certain limits and conditions general sanction was given for capital expenditure and employment of staff in cases where direct management by the Ministry was unavoidable. Some fifteen institutions were open in March, 1919, and a test examination has been applied to the accounts with generally satisfactory results. The altered conditions arising out of the armistice necessitated a review of the position and fresh proposals have accordingly been submitted to the Treasury.

Closing of an Important London Special Hospital.—Not a day goes by that the journals do not announce that several hospitals in different parts of the country are in grievous difficulties. A few days ago Sir Frederick Macmillan, chairman of the Governors of the National Hospital for the Paralyzed and Epileptic, Queen Square, Bloomsbury, London, when presiding at its annual meeting, commented on the grave financial straits of the institution. He stated that during the year 1919 the total expenditure of the hospital and convalescent home exceeded the income by nearly £7,000, the deficit being due to rise in prices. Either a considerable sum of money must be raised immediately or the hospital must be closed. If £10,000 could be raised this year and £5,000 for each of the next two years over the present income the debt could be liquidated and the hospital could be carried on until 1922. Appeal was, therefore, made for contributions toward the special maintenance fund, but in the event of failure to obtain promises the governors had determined to close the hospital with the exception of the out-patient department and possibly the surgical wing. The Convalescent Home, the pathological department, the school of massage, and the Annexes, Bray Court and Lonsdale House, which were either self-supporting or were paid for by the Ministry of Pensions, would be carried on. That such an institution as the National Hospital for Paralyzed and Epileptic should be menaced with closing, shows to how critical a stage the hospital situation in Great Britain has come. The Queen Square Hospital is the most important special hospital of its kind in this country and one of the most important in the world. It was in this institution that Hughlings Jackson made his discoveries and that Gowers made his name. It is especially notable for being the place in which that great surgeon and thinker, Victor Horsley, practically revolutionized brain surgery. When a hospital of the eminence and endowed with so great traditions is threatened with obliteration, it can truly be said that the time has come to reorganize the hospital system of the country.

Sanatorium Benefit Under the Insurance Act.—As mentioned in previous letters sanatorium treatment of tuberculosis has been taken away from the domain of the insurance committees. On March 25 last Lieut.-Commander Kenworthy asked the Minister of Health if he would state to whom and in what manner it was proposed to transfer the duty of providing sanatorium benefit to insured persons, hitherto performed by the insurance committees, under the provisions of the new National Health Insurance Bill. Dr. Addison, the Minister of Health, replied that institutional treatment for insured persons suffering from tuberculosis was already being provided in most areas by the public health authorities under agreements made with the Insurance Committees, and it was proposed to transfer the duty of providing such treatment to appropriate public health authorities. He said that he was hoping to introduce legislation for this purpose at an early date. Domiciliary treatment for insured persons suffering from tuberculosis would be provided by insurance committees under Clause 4 of the National Health Insurance Bill as part of the medical benefit.

LETTER FROM PARIS.

(From an Occasional Correspondent.)

PARIS, April 10, 1920.

DURING a recent visit to Marseilles, your correspondent had the good fortune to obtain some first-hand information relating to typhus fever as met with in the Serbian soldiers who developed the disease at Bizerte, Tunisia, in 1916, and the epidemic of 1917 which raged in Moldavia, Roumania. The following is a brief summary of what the French military physicians who were present at both these epidemics, have found and their conclusions cannot be devoid of interest to your readers. Their observations confirm the belief that neither fleas, bedbugs, nor ticks are the vectors of typhus and also that the sputum and mucous secretions and the dust of hospital wards are in no way dangerous and cannot propagate the disease.

Typhus fever has no symptomatology or any pathognomonic sign, in the strict sense of the word, belonging to it. The exanthema, formerly regarded as a constant sign, may frequently be absent. The eruption does not generally appear before the third to the fifth day, so that it does not help in making an early diagnosis. However, certain symptoms will permit the physician to make a diagnosis if he be on the lookout for them, namely, the peculiar temperature shooting to a point and followed by a remission on the second

day, the oculopharyngonasal catarrh and buccal exanthema. The clinical forms of typhus fever are varied. There is the medium form, the typhus levissimus or mild ambulatory type without exanthema, and lastly the petechial ataxo-adynamic form. The latter is by far the most serious of all whether it be marked by a predominance of phenomena of septicemic infection (cardiac symptoms) or of nervous intoxication (cerebral or bulbar phenomena).

The complications, which are numerous, are both medical and surgical in type, but they are to be dealt with by the classical treatment of these affections, independently of the general treatment of the case which, of course, must never be neglected. Morbid associations are not exceptional, especially in the greater epidemics. Typhus fever is an absolutely cyclical disease undergoing its evolution in fifteen days in the average case. The prodromes are often distinctly perceptible for those that know them, the incubation period being normally from seven to fifteen days, but the phenomena accompanying them may pass completely unnoticed if the attention of the subject has not been especially attracted by the bite of a louse. The patient presents a characteristic exanthema but which, it should be repeated, is often wanting. Unless some serious complication results in death or, on the contrary, prolong the affection by febrile manifestations quite independent from its evolution, defervescence occurs on the thirteenth or the fourteenth day of the disease. The patient then either recovers or dies. Death therefore is more prone to take place in hyperthermy, but it may occur in hypothermy, although there may be no intercurrent causal factor, such as associated cholera, for example.

Strictly speaking, typhus is one of the epidemic diseases of armies in the field but it also attacks the population of cities or the country as well, although no army may be present. The poor are the most commonly stricken and the well-to-do classes are less prone to be afflicted, merely because of better hygienic surroundings. However, physicians and nurses have been found to pay an enormous tribute to the disease. The mortality varies with the age, constitution and pathologic antecedents of the patient, the average being from 13 to 20 per cent, while in intellectual subjects—physicians in particular—it may attain from 30 to 40 per cent. One attack of typhus does not appear to confer an absolute immunity to the disease and recurrences, although rare, are quite possible.

In a fully developed epidemic the diagnosis is relatively easy but such is not the case when there is no epidemic. Reference has been made to the three cardinal initial symptoms and it may be added that the differential diagnosis of typhus from other toxi-infectious processes is relatively easy. The seroreactions which have so far been proposed as specific are valueless and laboratory examinations only result in negative data but permit one to eliminate other febrile diseases. Certitude can only be had by guinea-pig inoculation, especially when this is done in series, but the result will be known only after the clinical evolution of the typhus fever will have taken place in the patient, but it will allow the physician to make a *retrospective* diagnosis, the importance of which is always great from the viewpoint of prophylaxis. This diagnosis can be made after recovery of the patient—even a very long time after—by merely looking at the subject from the difficulty in walking, the ankylosis of the joints, the insomnia and pain in the limbs which is particularly marked at night.

Experimental research work and microbiological studies have not as yet given any conclusive results in respect to the pathogenic agent of typhus fever. It is supposed to be a protozoön since we now know that the louse is its intermediary host. However this may be, the various bacteria which have been described have now been recognized as simply symbiotic agents of the specific organism yet to be discovered. At all events, this unknown virus appears to belong to the category of filtrating virus and in all probability it is fixed in the white corpuscles of the blood. The changes in the red blood corpuscles described by some observers do not appear to be in any way specific. All the viscera of guinea-pigs experimentally infected contain the virus during the febrile period and Nicolle of Algiers has realized its unlimited preservation by successive passages in this animal.

The treatment of typhus is above all prophylactic: deparasitation and hygiene. Next it is symptomatic and deals with the clinical manifestations while lastly, serotherapy may be resorted to. Various sera have been essayed, serum from convalescents, from patients in the height of the disease and experimental sera, but of all the procedures so far advanced, that of Nicolle is the only one worth retaining in practice. Unquestionably, this serum cannot be regarded as specific because the true agent of typhus is still an unknown quantity, but until it has been discovered it would seem from reports that the antiexanthematic serum should be used in the treatment of this dire morbid process, combined with all the other resources of general therapeutics.

PRACTICE OF HYGIENE IN PLACE OF PREACHING.

To the Editor of the Medical Record:

Sir:—The public and the medical profession are getting thoroughly convinced that a department for the use of passive and active exercise as a means of restoration of health and prevention of disease should be established upon a recognized standard. If the hospitals include this undertaking, such work will be under scientific supervision and will give the desired results.

If it is not practical to embody such a department in existing institutions, an equipped pioneer institution should be planned, which should be self-supporting and economically independent.

This work in European countries is an applied science that has the indorsement of medical authorities. They consider it a means of vital importance for assistance in completeing their work for health and reconstruction.

C. Carman Harriot.

2. The "Common Cold" in Relation to Certain Microorganisms, and Its Treatment with Bacterial Vaccines.—Cleaveland Floyd uses the term "common cold" to designate the infection of the various respiratory passages seen so commonly in this part of the country in the winter. The results of many recent observations, he says, point to the predominant place of members of the streptococcus and pneumococcus groups in the etiology of infections of the upper respiratory tract. He suggests a general classification of the various types of the "common cold" based on fairly constant bacteriological finds. The production of an active immunity through the use of appropriate bacterial vaccines will be of value prophylactically, he thinks, in the control of infections of the upper respiratory tract. The method devised has been as follows: The isolation of members of the staphylococcus, streptococcus and pneumococcus from cases where the infection has been severe, and the preparation of bacterial vaccines from each one of these types of organisms. Therapeutically, early in the fall, three or four inoculations are given of a combination of the vaccines of the streptococcus and staphylococcus groups. In the early part of the winter a second series of inoculations is given with a combination of the vaccines of the members of the streptococcus and pneumococcus groups, and this is repeated in the early spring. Should a cold develop in the interim, the patient is urged to present himself for inoculation during the first twelve hours of the onset of the infection. One or two inoculations will occasionally bring the cold to a rapid termination. In those cases where abortive colds appear, or where, in spite of inoculations, an extensive infection develops, microorganisms are studied in each instance, and autogenous preparations made and used in subsequent inoculations. The results of this method have been in some instances unsuccessful, but in the majority the inoculations have materially modified the severity of the types of colds usually endured, and have diminished their frequency. In some individuals practical immunity from acute respiratory infections has been secured. This has been especially the case in those individuals who have an abnormal susceptibility to this type of infection and in whom it is not uncommon to see one cold rapidly succeeding another.

8. The Evils of Fixed Bridge Work. Herman E. S. Chayes
9. Notes on Mouth Sepsis. Lester R. Cahn.

2. The Present Status of Oral Sepsis in Relation to Medical Diseases.—James M. Anders holds that a closer cooperation, better team work, between dentist and physician is urgently needed in order to set at rest many questions bearing upon the etiological relationship of mouth to systemic infection. In any case of oral sepsis in which constitutional symptoms are found in association, the dental surgeon should report both the *x*-ray findings and those of the bacteriological laboratory to the physician in charge. While the writer favors consultations between dentists and physicians in cases of tooth root disease with their symptoms manifested by outlying organs, he calls attention to the fact that the recent developments in so-called focal infections have thrown added responsibilities upon the dental profession, and these should be recognized now, and fully met in the immediate future. When the time arrives that a complete report from the dentist is available to the physician, it will be incumbent upon the latter to show the connection between the local and general morbid states, including their symptoms. It will be the clear duty of the internist to demonstrate the presence of an identical organism or its pathological effects, in the affected organs outside of the mouth cavity. In this way, and in this way only, can real progress be made that will be of mutual advantage to the dental and medical professions. In this way also may it be hoped to arrest the serious blunder of sacrificing useful teeth. The scientific study of mouth infection from the viewpoint of diagnosis can never reach the high plane which its dignity and importance demand so long as it does not receive the continual impetus resulting from combined laboratory and clinical methods. It follows that every progressive dentist and physician must utilize the advantages offered by a private o public bacteriological laboratory, so as to be able to make an etiological diagnosis whenever possible. The question of the prevention of tooth root disease should be preeminent in the minds of all who are interested in the health and welfare of the race. This must come through education and enlightenment, especially with regard to the cleanliness and care of the masticating apparatus. An abscess about a tooth root which cannot be freely drained should not lead to the immediate extraction of the organ; apiectomy, if required, whenever feasible should be undertaken. In the treatment of an abscess that can be drained the preparation and use of an autogenous vaccine is to be advised, with the object and assurance of shortening the disease. Among the various morbid medical conditions of oral origin, as shown by the fact that correction or removal of the chronic focus about the teeth has effected a cure, or at all events, a well marked and immediate amelioration of the symptoms, the writer mentions arthritis, endocarditis, pericarditis, myocarditis, myositis, gastritis, gastric ulcer, myocardial degeneration, arterial fibrosis, chronic nephritis, and exophthalmic goiter.

1. Operation and Reoperation for Gallstone Disease.—John B. Deaver discusses the question of recurrence of symptoms after the surgical treatment of affections of the gallbladder and the biliary passages, with report of pathological research by Stanley P. Reimann. In a previous report on more than a thousand operations on the gallbladder and the biliary passages Deaver found that 4.07 per cent. were reoperative cases, some of the patients having had three operations. Among 800 cases coming under his observation since January, 1916, 8.5 per cent. (seventy cases) were secondary (there were also a few tertiary) operations. Of the recent series, fifty-one patients were originally operated on elsewhere by other surgeons, the remaining nineteen having been operated on by the writer. In thirty-six of the fifty-one, recurrence took place after a cholecystostomy and fifteen after a cholecystectomy. The longest interval between operations was fifteen years. The average interval between operations in this group was about five years and nine months, the average period of freedom from symptoms being about two years and three months. In his per-

sonal series it was found that in eight cases the symptoms recurred after primary cholecystostomy, one after choledochostomy, and ten after cholecystectomy, or 1.3 per cent. after removal and 10 per cent. after drainage operation. Excluding the fifty-one cases of the first group (in which the patients were primarily operated on elsewhere), a primary cholecystectomy was performed in 611 and cholecystostomy in 78 cases; other primary operations consisted of cholecystoduodenostomy, 27; choledochostomy, 11; choledochoduodenostomy, 1; exploratory, 16; pancreatostomy, 4; and duodenotomy, 1. The longest interval between operations in the drained cases was fourteen years, the shortest one month, with an average of six years and four months, while freedom from symptoms averaged three years, the longest period being thirteen years and the shortest one month. Of the fourteen patients whose gallbladders were removed, five remained well for a period varying from two months to two years, two were not benefited by operation, and seven required secondary operation during convalescence. The great variance between recurrence after radical surgery of the gallbladder and those that take place after conservative surgery leads to the manifest conclusion that radical treatment gives the greater prospect of a permanent cure. From the pathological studies it is concluded that the peraticular streptococci recovered from human gall bladders and injected intravenously into rabbits showed no elective affinity for the gall bladders of the animals; at least not with one injection of what seemed an adequate number of organisms. This conclusion in itself, however, does not negative the importance of the streptococci in the human gall bladder. With streptococci in the gall bladder, a chronic toxemia may be present for long periods of time; a constant stimulus for lymphangitis and connective tissue proliferation is present, and an opportunity for a general bacteriemia is always at hand.

6. Army Hygiene in the Future. Sir John Goodwin.

1. The Late Results of the Surgical Treatment of Chronic Ulcers of the Stomach and Duodenum.—James Sherren summarized this Hunterian lecture delivered before the Royal College of Surgeons of England on February 11, as follows: While gastrojejunostomy combined with general abdominal exploration and dealing with other diseased organs is curative in the majority of cases of chronic duodenal ulcer, each must be studied, and those eroding the pancreas or spreading to the stomach removed. Gastric ulcers which have perforated and are adherent to neighboring organs, indurated ulcers on the lesser curvature, and all in which there is any suspicion of malignancy, must be treated by partial gastrectomy. Gastrojejunostomy for chronic ulcer will become the less frequent operation. Symptoms arising later if the correct operative procedure has been adopted are due to mechanical or ulcerative changes in the region of the anastomosis, both prevented by careful technique, in the majority of cases, and becoming less frequent as individual experience ripens.

3. The Problem of the "Positive Throat" in Diphtheria Convalescents.—James Law Brownlie, from a clinical study of fifty consecutive vaccine-treated cases, concludes that local antiseptic throat applications are unreliable for the carrier and the positive throat. Diphtheria vaccine produces well-defined degeneracy in morphological appearance of the cultured organism, followed by its complete dispersal from the locality invaded. In the past the diphtheria carrier has been subjected to hospital residence for weeks, perhaps months, which were avoidable. Diphtheria vaccine is effective in the treatment of the positive throat convalescents, and its use is administratively and economically sound.

8. Treatment of Gonorrhea in Women. R. Stafford Foss.

1. Abdominal Emergencies.—Professor Rutherford Morison holds that in every case of abdominal emergency for which one may be called the patient has abdominal pain. The first question to be answered is whether this is due to some serious cause or not, and that can often be decided, if the patient is seen in the early stage, after a single look. "Abdominal facies" is an important aid to diagnosis for the observant clinician. At the commencement of every serious abdominal emergency there is "shock," and this produces effects so obvious as to alarm the patient's friends. It is well to listen to their story, because in some cases "shock" very quickly disappears and a stage of reaction follows, when recovery may appear to be so complete as to deceive the most wary. This occurs even in such serious and hopeless conditions as lacerations of the hollow viscera by injury and perforations of gastrointestinal ulcers. Operation within six hours would save 90 per cent. of these patients; the policy of "wait and see' 'allows 90 per cent. of them to die. In the reactive or second stage the patient may look and feel so much better that it seems almost impossible that there are serious results to follow. Now is the time when the diagnosis is most difficult, and often most important, and it may be impossible to answer the first question one must ask oneself, namely, whether the condition is or is not a serious one. The third clue is to be found in the history of pain. The causes of abdominal pain are special to the abdomen. Illustrative cases are cited to show the significance of irritation of the peritoneum, forcible contraction of unstriated muscle, and dragging on the mesentery (torsion). Rigidity of the abdominal wall is a physical sign of great importance. Intraabdominal hemorrhage is a serious abdominal emergency, of which pain is usually the first symptom, whether it be caused by injury or not. Relief of pain is what the patient demands, but before giving either a hypodermic injection or morphine or any purgative it is essential to determine whether or not the case is a serious one. A rise in the pulse rate is the most important sign of progressive mischief, and in doubtful cases the pulse rate should be noted every hour. Operation offers the only reasonable chance in an overwhelming majority of serious cases, and its chief objects, in the abdomen, as everywhere, are (1) to arrest hemorrhage, (2) to remove or exclude a focus of disease, and (3) to deal with mechanical obstacles. Every patient with a more than ordinary pain in the abdomen ought to be sent for observation, and. if needful, operation, to a properly equipped hospital without delay. It is always to be remembered that abdominal pain may depend upon conditions not strictly surgical, and the advantage of a physician's cooperation should not be lost sight of. The writer suggests the following list of possibilities: 1. Irritation of the lower six intercostal nerves, resulting from pneumonia, pleurisy (purulent or otherwise), pericarditis, herpes zoster, growths or caries of the vertebræ, locomotor ataxia, and hysteria. 2. General toxic conditions, such as arise from chronic kidney disease, diabetes, Addison's disease, Henoch's purpura, ptomaine poisoning, lead poisoning, typhoid fever. 3. Abdominal conditions, such as pyelitis, kidney and ureter stones, tuberculous lymphatic glands, and especially acute dilatation of the stomach, and in women, dysmenorrhea. The most common cause of an abdominal emergency is appendicitis. Acute intestinal obstruction, perforation of stomach and duodenum, gallstones

and cholecystitis, ovarian cyst with twisted pedicle, and ectopic gestation are other conditions considered in this connection.

5. **Appendicitis Without Protective Stiffening of the Abdominal Wall.**—John D. Malcolm calls attention to the fact that the importance of protective contraction of the abdominal wall over the cecal region as an indication of appendicitis is sometimes exaggerated. He cites a case in proof.

Radiation Treatment of Uterine Myoma and Hemorrhagic Metropathy.—Boije has treated 52 cases of myoma and 14 of metropathia hemorrhagica with *x*-rays. Of the former the hemorrhage was checked in 83 per cent., while in 8 patients it was not checked but brought to normal limits. In 95 per cent. of cases studied the tumors were contracted to a minimum or materially. In a few cases these were hardly palpable. In but one of the 52 cases was the result entirely negative. There was one case, however, in which it was decided to operate and one patient vanished from observation, so that the end result was in doubt. The observation period lasted from 4 months to 5 years. Of 14 cases of metropathia hemorrhagica complete amenorrhea was obtained in 9, while in 4 normal menstruation was secured. The other patient vanished from observation. The author, in view of these superior results, recommends the method when by reason of myoma heart or other complication the knife is contraindicated. Radiation is contraindicated in secondary degeneration of myoma and in polypoid, submucous and other operable cases. The pains of myoma yield rapidly to radiation in cases under examination. If the patients have flowed to the point of anemia and narcosis is contraindicated, the tumors may be rayed until the case becomes operable. Generally speaking radiation is not desirable in young women and should be thought of only after the age of 40. This side of that age even a palliative operation is better than the rays. In cases for radiation before climacteric years one should not seek to suppress the flow of blood outright but only to bring it within the bounds of normal menstruation.

Treatment of Burns Since the Close of the War.—Rozieès writes on a timely theme which involves the reputation of the so-called ambrine and its numerous substitutes and congeners. Most practitioners to-day are using picric acid and the ointment of Reclus. A number of other substances of the most opposite type have more or less value. It is clear that we must have something more than empiricism as a guide to arrive at any standardization. Resin of amber is sedative and keratogenic at the same time, or in other words, both analgesic and cicatrizant. The alleged benefits derived from the routine use of the ambrine type may be omitted as already well known. They at least give a line on the nature of a remey for burns which should possess the qualities mentioned above. Sunlight is said to possess both of these and is useful *per se* and as an adjuvant to the dressing. Treatment of burns by this resourse is an old subject and was written up in 1904 by Bernhard. It may be begun after the subsidence of the acute symptoms or about 5 days after the injury. A third mode of treating burns is founded on the prevention of adhesion to the dressings. Before the late war Quénu had recommended the use of silk. After initial disinfection with weak sublimate (1-10,000) the silk is applied dipped in ordinary serum. Another resource is tulle which has been smeared with some soothing substance—vaseline, wax, castor oil, balsam of Peru, etc. Tulle already prepared in this manner may now be procured. The author has had two cases in which this prepared tulle gave perfect results in sedation and cicatrization.

La Riforma Medica.

February 14, 1920, xxxvi, 7.

Grippal Meningoencephalitis.—Pace gives two cases of this affection from the clinic of Prof. Cadarelli, which is referred to as extremely rare. One is as follows: Housewife, aged 36, was still in hospital recovering from an operation for prolapse when she was attacked suddenly by fever, headache, delirium, and motor agitation. On the third day was transferred to the medical side in full delirium. Diagnosis hesitated between malarial fever, central pneumonia, and primary cerebral grippe. Rachicentesis brought away clear fluid under high pressure and was followed by singular improvement, temperature falling two centigrade degrees to nearly normal. The microscope showed a classical lymphocytosis. Another case seen about the same time closely resembled the preceding, but in the second the cerebral affection was not primary, but a sequela of an attack of ordinary influenza. The patient also developed a comatose instead of delirious state, and it was necessary to exclude uremia and apoplexy. The patient was subjected to venesection and spinal puncture and the latter, as in the first case, was followed by great relief and the punctate showed the same qualities. As both patients recovered it was hardly possible to clinch the diagnosis, but the second case was plainly grippal, and the resemblance of the first to the second was striking. From what we know of autopsy cases, together with certain data concerning the punctates, the probable lesion is meningoencephalitis. Of such interest is the fact that these cases do not bear any resemblance to any of the many types of lethargic encephalitis. Coma in the latter has been only terminal coma in the fatal case.

La Riforma Medica.

February 28, 1920, xxxvi, 9.

Magnesium in Cancer.—In an editorial note it is stated that the tumultuous proliferation seen in a neoplasm is believed by Boveri to be due to a defect of chromosomes. There may be many factors which can determine the proliferation which may also be visualized as a defense phenomenon. It is claimed that the disequilibrium is aggravated by the monovalent alkalies and antagonized by the bivalent calcium and magnesium. The elderly are said to be defective in reserves of magnesium. The power of magnesium locally applied over warts and even malignant papilloma in dogs is ascribed to reconstitution. The author quotes from an article by Dubard published during 1919 on the magnesium theory of cancer, which has been reproduced in part in various journals, but is not accessible in the original. The paper in question was published in *La Bourgogne Médicale* for July 15, 1919, and it is not known that any of the alleged finds have been substantiated. Dubard has seen magnesium waste in the urine during cancer. Shortage of this element in the organism is felt notably in the nervous centers, especially in the grey matter, and is attended by neurasthenic depression and diminished functional capacity. This has heretofore been attributed to waste of phosphoric acid, but apparently Dubard accuses the loss of the magnesium in the phosphates. Dubard has given a mixture of calcined magnesia, sodium fluoride, manganese binoxide (both the latter in minute amounts only) and phosphoric acid over a period of 6 or 8 months with alleged good results. In the cerebral affection it is possible that magnesium only acts by fixing the phosphorus.

Fleas and Contagion.—Ferrari not only believes that fleas play a rôle in the spread of smallpox, measles, and scarlet fever, but asserts that this flea transmission offsets some of the benefits of vaccination. He would thus explain why a considerable number vaccinated within ten years from a given date contract the disease during its epidemic incidence. The revaccinated, while they are relatively immune, present not a few cases of mild variola during epidemics. The inference is that vaccination ought always to be associated with vigorous house to house fumigation to abolish the insect menace. This view, he says, is now that which obtains in Germany, for while the flea has not been specifically accused in that country, house fumigation is practised with good statistical results as a necessary part of prophylaxis in association with vaccination.—*Brazil Medico.*

Book Reviews.

A Concise History of Medicine. By Sir William Osler, M.D., F.R.S., Regius Professor Medicine in the University of Oxford. Baltimore, Md.: Published by permission of the Encyclopaedia Americana Publishing Co. by The Medical Standard Book Co. 1919.

The distinguished author begins with the time of Boerhaave, Morgani, Haller, Cullen, Hunter and Hahnemann, these men serving rather to give the impetus to modern medical thought than to make actual contributions to modern practice. They were succeeded by Laennec, Bright, and a school of similar clinicians. The subject matter now becomes limited to the United States and the students of American fevers and other autochthonous maladies, the founders of medical schools and American medical philanthropy. The author passes to laboratory research, specialism—with especial regard to alienism—and organized prophylaxis, the latter being founded on bacteriology and parasitology. These branches, since they represent the keystone of the arch, receive proportionate space. Next follows an account of the progress made in stamping out the great plagues, fourteen of which are discussed in detail. The essay closes with a few paragraphs on modern therapeutics as contrasted with those of former years, drugs and depletion having been succeeded largely by dietetics, physical therapeutics and mental measures.

The Medical Aspects of Mustard Gas Poisoning. By Alfred Scott Warthin, Ph.D., M.D., Professor of Pathology and Director of the Pathological Laboratories of the University of Michigan, Ann Arbor, Mich., and Carl Vernon Weller, M.S., M.D., Assistant Professor of Pathology, University of Michigan, Ann Arbor, Mich. With 156 original illustrations. St. Louis: C. V. Mosby Company. 1919.

The investigations which form the basis of this volume were begun as an independent war research problem in 1917, and were continued when the Pathological Laboratory of the Medical Department of the University of Michigan became associated with the Medical Advisory Board of the Chemical Warfare Service. The various individual reports have been gathered together, corrected and expended to form the chief part of this volume, which covers, with bibliography and index, 267 pages. The eight chapters include the medical aspects of gassing in warfare, the cutaneous lesions produced by mustard gas (dichlorethylsulphide), the ocular lesions, the lesions of the respiratory and gastrointestinal tracts, the general pathology, the clinical pathology, the treatment of the injuries, and a general summary of dichlorethylsulphide poisoning.

Nervous and Mental Diseases. By Archibald Church, M.D., Professor of Nervous and Mental Diseases in Northwestern University Medical School, Chicago; and Frederick Peterson, M.D., formerly Professor of Psychiatry, Columbia University. Ninth edition, revised. With 350 illustrations. Philadelphia and London: W. B. Saunders Company, 1919.

For twenty years this book has been a favorite with students and practitioners. It is, in reality, two monographs; each author being responsible for his own section. The present revision presents no radical changes. The subjects of General Paresis and Traumatic Insanity have been rewritten, and various additions and corrections have been made. The style is attractive, and the authors have presented their facts clearly and concisely; at the same time they have been careful not to include the numerous radical views and fads which have not yet met with more than a limited acceptance. In another edition some mention should be made of: Cerebrospinal fluid, wet brain, choked disc, Brudzinski's sign, vagotonia, catalepsy, and method of re-education; these terms are not in the index of the book.

The Opium Monopoly. By Ellen N. La Motte. New York: The Macmillan Company, 1920.

This volume is written without bias and the data are drawn from government sources. The reader may doubtless have been led to believe that the evils depicted had been suppressed or at least repressed, but it is only the enlightened communities of Europe and America which have been hostile to the opium traffic. In the Far East there is apparently no great moral struggle. Business men and the consumer both sanction the traffic which is a matter of supply and demand. The author sketches the opium traffic in Hindustan, Japan, Singapore and the Straits Settlements, Siam, the great Chinese seaports, Turkey and Persia, Mauretius, British North Borneo, etc., and in the Western Hemisphere, British Guiana. The British and Indian monopolies, the traffic in modern Japan and in China before the reform movement are outlined. There is no opium problem in Australia, New Zealand and the Philippines while in China it is limited to the treaty ports, etc.

A Manual of Obstetrics. By John Cooke Hirst, M.D., Associate in Obstetrics, School of Medicine, University of Pennsylvania; Obstetrician and Gynecologist to the Philadelphia General Hospital; Obstetrician to St. Agnes Hospital; Gynecologist to Mount Sinai Hospital; Gynecologist to the American Hospital for Diseases of the Stomach; Fellow of the College of Physicians, Philadelphia. With 216 illustrations. Philadelphia and London: W. B. Saunders Company, 1919.

This little volume is intermediate in size and contents between the compend and the text-book. The author has managed to include everything of importance and has carefully avoided unnecessary and unprofitable discussion. The book presents the modern ideas and teachings on the subject of obstetrics, it contains only the very essential points of embryology, and the pathology of the new-born infant is limited to the puerperium. The author writes clearly and concisely, and has not forgotten the difficulties of the beginner. Among the chapters which are of special interest may be mentioned those on the mechanism of labor, hemorrhages, and the forceps. The illustrations are well selected. As a first book on the important subject of obstetrics, this volume can be warmly commended to medical students.

A Manual on Foot Care and Shoe Fitting. For Officers of the U. S. Navy and U. S. Marine Corps. By W. L. Mann, Ph.B., A.M., M.D., Lieutenant Commander (M.C.), U. S. Navy, Post Surgeon, Marine Barracks, Quantico, Va., and S. A. Folsom. M.D., Lieutenant (M.C.), U. S. Navy; Medical Officer in Charge of Orthopedic Division. Medical Department, Marine Barracks, Quantico, Va. With 58 illustrations. Philadelphia: P. Blakiston's Son & Co., 1920.

This booklet contains much valuable information and illustration, the text of which from the small compass allowed is given in very condensed form. There is no logical arrangement into chapters or other divisions, the matter having been arranged by subjects *seriatim*. There are numerous sections headed "shoe fitting" of which the first appears to be a misprint for sock fitting. The book deals with the foot, the shoe, the sock, the diseases and deformities of the foot and the detailed technics of shoe fitting.

The Systematic Development of X-Ray Plates and Films. By Lehmann Wendell, B.S., D.D.S. Chief of Photographic Work, Instructor of Prosthetics and Orthodontias, College of Dentistry, University of Minnesota. St. Louis: C. V. Mosby Company, 1919.

The nine chapters of the book are devoted respectively to the Introduction, Fundamentals, Methods of Development, Developing Formulas, Alteration of the Negative of Chemical Means, Tanks, Chemicals, Useful Suggestions, the Darkroom and Lantern Slide Making. The book therefore conforms to manuals of ordinary photography. There are 33 figures which include *x*-rays of bones and especially teeth and photographs and cuts of apparatus. The book is intended to fill an unoccupied space in *x*-ray literature and the author appears to have well performed what he attempted.

Le Ferite del Retto. By E. Ricciolli, Bologna: L. Cappelli, 1919.

This brochure of 65 pages, well illustrated by photographs, is based in part on personal experience with seventeen military cases of wounds of the rectum, which were often badly complicated. It is certain that these injuries are very rare and that nearly always the subject is badly wounded, usually in the vicinity of the rectum and at times at a distance from the same. There are no pathognomonic symptoms and the diagnosis is made only after careful examination. Death occurs as usual from shock, hemorrhage, sepsis or peritonitis.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventy-first Annual Session, Held in New Orleans, April 26-30, 1920.

(Special Report by Telegraph to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

DR. HUBERT WORK OF PUEBLO, COLO., SPEAKER, IN THE CHAIR.

First Day—Monday, April 26.

President's Report.—Dr. ALEXANDER LAMBERT presented this report, which was devoted to a discussion of the hospital situation and urging the association to take a greater interest in hospital development. For a number of years this interest had been evinced in making the hospital not merely a place in which to treat the sick, but an institution playing a prominent part in medical education and closely linked up with the medical schools. In order that it might meet these requirements there should be at its head a man with a combination of medical and executive ability. It had been recognized for some years that to develop hospital organization properly so that the hosiptal might fulfill its various functions as an institution, there should be some association or body composed of the various agencies interested in different branches of hospital work. A conference of a large number of such organizations was called in Cincinnati last year in the hope that they would form an association for the purpose of developping the hospitals as they should be developed. This effort was not successful. The subject, however, was of such importance to the medical profession that they should lend their support to it. This was first recognized by the American College of Surgeons, which had undertaken to formulate a standard for hospitals as regarded equipment and technique. At present but 20 per cent. of the hospitals in the United States had an interne service; 80 per cent. of the smaller hospitals did not have internes. As the council on education of the American Medical Association had done such effective work in standardizing medical education it would seem that they should undertake the work of hospital standardization and development along similar lines. A question that came up was whether to put this work under one of the councils or bureaus already in existence or to create a new council. This question had been discussed by the trustees and the majority favored the creation of a special council. In this work the cooperation of the various special societies interested in special activities connected with hospital development should be sought. Physicians should also be interested in the nursing question, which was so vitally connected with hospital work. The American Medical Association could little afford to stand aloof from this undertaking. The president recommended the creation of a standing committee on hospital standardization and development to be known as the Council on Hospitals, and that the by-laws be amended so as to provide for such a council.

Secretary's Report.—Dr. ALEXANDER CRAIG of Chicago presented this report. It stated that the members of the various constituent State associations on April 1, 1920, numbered 83,338; the fellowship of the scientific assembly on April 1 was 47,045, being a net increase in eleven months of 1,633. It was recalled that last year comment was made relative to the activity of the association in assisting physicians formerly in military service to resume their civil practice, and the universal opinion was that physicians were receiving a hearty welcome in localities where they formerly practised. It was gratifying to know that the organized profession had met the obligation which was then anticipated, and that in large part the members of the Medical Reserve Corps had again taken up civil practice. There were now other obligations somewhat similar in character to be undertaken, new economic and civil relationships which were of peculiar interest to individual practitioners. In all these questions the association must taken an active interest. In order to cope with these problems it was advisable to strengthen the organization wherever possible by concerted effort to increase membership. There was a possible danger from a multiplicity of organizations in the same territory having practically the same object. In a few instances new organizations had diverted from county and State branches the activities of certain members who had previously taken a prominent part in county and State work. It had been proposed that financial support should be given to certain of their new bodies which otherwise might deprive branches of the American Medical Association of funds which if available could be used through regular channels of State and county organizations. This matter was brought before the house in order that it might be brought to the attention of State associations and county societies and that all branches of the organization and members of the medical profession should be urged to devote themselves to the advancement as well as the extension of county, State, and national bodies.

Report of the Board of Trustees.—Dr. PHILIP MARVEL of Atlantic City, N. J., presented this report. In these times of unusual political and social unrest, matters of the association were progressing satisfactorily. The detailed statement showed that 3,760,351 copies of the *Journal* were printed in 1919, the average weekly circulation being 74,919, an increase of 7,375. The first year of the Spanish edition had been reasonably satisfactory, the subscription list being 2,908. It was published at a loss, however, of a little less than $10,000. The report reviewed the status of the special journals published by the association and stated that it was proposed to commence the publication of the *Archives of Surgery* in July. It was planned to publish this bi-monthly at first. An appeal from a large number of physicians had been made for a special journal to take the place of the *American Journal of Obstetrics and Diseases of Women and Children*, but the present condition of the printing plant did not warrant undertaking this. The report intimated that it might be necessary to raise the prices of all the journals a dollar a year each. The cooperative Medical Advertising Bureau was no longer an experiment; it was a great success and was so regarded, it was believed, by all the State journals it represented. The bureau had demonstrated that it was possible to secure for these journals a fair amount of advertising, of which neither the journals themselves nor the medical profession need be ashamed. The bureau had removed the temptation to accept that class of advertising which for so many years had been not altogether creditable. With reference to the work of the Council on Pharmacy and Chemistry, a suggestion had been made last year that there be closer cooperation between the large pharmaceutical houses and the Council on Pharmacy and Chemistry. In reply to this a statement was submitted to the effect that when the Council was organized it was hoped that all the large pharmaceutical houses would find it possible and desirable, if not actually more profitable, to cooperate, and to shape their business methods so as to make their proprietary and other articles conform to the conservative standards upon which the council based its rules, and thus render such articles acceptable for "New and Unofficial Remedies." They had been disappointed in this hope, for many pharmaceutical houses were not only unwilling to cooperate, but in many instances actually exhibited definite antagonism. Evidently the problem had resolved itself into this: The Council, constituted of scientific men, working without remuneration in the interest of scientific medicine and the medical profession, expected and rightfully, the cooperation and support of the members of that profession. What was needed, therefore, was active, sympathetic cooperation of physicians; then the cooperation of the pharmaceutical houses would follow as a matter of course. The interest of the profession and public in the work of the propagander department was increasing. During the past year the department had received more inquiries from newspapers regarding medical "copy" than ever before, and had also had an unusually large number of inquiries relative to itinerant quacks. In reply to these inquiries data were furnished which in many instances sufficed as a basis for action that had materially protected the public: in some instances the

information was used as the basis of legal action against quacks. The department also had answered a remarkably large number of inquiries from schools and colleges, showing the degree of attention that teachers were giving to the nostrum evil, and the knowledge they had of the availability of the propaganda department's educational material. More than the usual number of inquires had been received regarding these patent medicines, whose most potent ingredient was alcohol. Pamphlets, educational posters, and stereopticon slides that had been prepared and issued by the propaganda department continued in active demand. One of these pamphlets was considered of sufficient importance to be introduced into the records of a government committee that was considering a bill designed to restrict advertisements relating to the treatment of venereal diseases and of certain sexual disorders. A new edition of "Nostrums and Quackery" was in the hands of the printers and would be issued shortly. This department of the *Journal* continued to justify its existence. As a clearing house for information on subjects with which it dealt it had proved a boon alike to the profession and the public.

The Treasurer's Report, which formed a part of the report of the Board of Trustees, showed the reserve fund of the association on December 31, 1919, to be $283,186. The surplus at the beginning of the year amounted to $471,661.50, and the surplus at the end of the year amounted to $456,839.39, a decrease of $14,822.11.

Report of the Judicial Council.—Dr. M. L. HARRIS of Chicago submitted a revised copy of the constitution and by-laws which at first sight, he said, might give the impression that many radical changes had been made, but upon closer investigation it would be seen that such was not really the case. During the past few years of evolutionary development of the association quite a number of changes had taken place in the character of the work done, as well as in the manner of doing it. Some of these changes, while fully recognized, had not been clearly set forth in the by-laws. The constitution likewise had failed to state correctly that character and form of organization. Opportunity had, therefore, been taken to define the organization as it really was and had been since the reorganization in 1901. Verbiage had been changed in many places for the purpose of clarification and to eliminate ambiguity and duplications, but there were no changes made in principles or fundamentals. During the past year the council had been collecting data on the subject of old age and invalidity insurance for members of the association. A brief questionnaire had been sent to the secretary of every county medical society affiliated with the organization. The questionnaire asked for information as to the number of physicians in the county dependent on financial aid and as to how many of that number were members of the county medical society, also the number over 65 years of age dependent because of age, with the age of each, if known, and the number under 65 dependent because of physical disability, with the cause of physical disability, if known. Reports were received from every State in the Union, and covered 53.48 per cent. of the total number of physicians in the entire country, or 77,083 of the 144,116, estimated total number of physicians in the country. One hundred and fifty-six were reported to be dependent on financial aid; 120 on account of old age, and 36 on account of physical disability. Only 42,824 of the 77,983 reported were members of the American Medical Association, and of this number less than 2 per cent. were dependent. In studying these statistics one was impressed by the remakably small number of dependent physicians.

Dr. Harris did not think it an appropriate time to consider changes in detail and suggested that these be taken up after the report was returned from the Reference Committee. Old age pensions might be treated as a local matter that could be left. so far as the financial side was concerned, with State and local organizations.

Report of Council on Health and Public Instruction. Dr. VICTOR C. VAUGHAN of Ann Arbor, chairman, called attention to the report of 1919 in which it was stated that one of the more urgent needs in the present public health situation was an increased knowledge regarding organized and official public health activities as a basis for constructive legislation. In 1914 the Council said the necessity for such an investigation need hardly more than be stated. The American Medical Association stood unreservedly pledged to the securing at the earliest possible moment of an adequate national health organization. No careful study had ever been made, from a legal standpoint, of the exact limitations of the federal government along public health lines. What could the national government do under the constitution for public health? No one was to-day in position to answer this question authoritatively. As a result, bills were drafted and measures proposed that would probably, if adopted, be unconstitutional, while such measures as the Harrison narcotic law, a law intended solely for improvement of public health conditions in broader sense, were passed ostensibly as revenue measures and were later by amendment converted into revenue producing measures with serious injustice and inconvenience to law-abiding physicians. If Congress had power to regulate the sale of habit-forming drugs for the public good, then it was not necessary for Congress to pass such measures under the guise of revenue laws which, after their passage, were distorted and misconstrued by federal officials into unfair and inequitable revenue-producing measures. This country would never have a federal department of public health such as had been advocated rather vaguely for fifty years past, until public health functions and powers of the federal government under the Constitution had been definitely determined. Two questions must be answered: First, What could the federal government do for public health; and, second, What was the federal government now doing for public health? These questions were not at present being considered by any other organization, yet their solution was the fundamental development of public health in this country.

Following the Atlantic City meeting, at a joint committee from the Council and the executive committee of state health officers, an agreement was made to cooperate in endeavoring to secure a reorganization of federal public health agencies. The possibility of the Council undertaking a survey of public health work was discussed and this led to realization that any such survey carried on by private or unofficial agencies would be neither constructive nor authoritative and that such an investigation could be made only by a commission created by act of Congress authorized and empowered to summon before it heads of the various bureaus and departments, and to call for official reports, estimates, records of expenditures, etc. A careful study of the situation in Washington, together with an inquiry that the legal and parliamentary questions involved, showed that the best form of securing the end sought was by means of a joint concurrent resolution. Such resolution was accordingly drafted and introduced into the Senate by Hon. Joseph E. France of Maryland, as Senate joint concurrent resolution 14, and into the House by Hon. E. E. Denison of Illinois, as House joint concurrent resolution 33. The resolution provided for a joint committee to consist of three members of the Senate and three members of the House "to make a survey of and report on these activities of the several departments, divisions, bureaus, offices, and agencies of the Government of the United States which relate to the protection and promotion of public health, sanitation, care of the sick and injured, and collection and dissemination of information relating thereto." The committee was directed to report to Congress. This resolution passed the Senate on December 20. The New Orleans session of the American Public Health Association endorsed the action of the joint committee, urging the passage of the resolutions by Congress and authorizing the appointment of a committee to cooperate with the joint committee in securing the passage of this resolution. The committee thus created formed an effective means whereby the combined influence of three organizations could be utilized for constructive public health work. The Council felt that for the first time in the history of the association it was on the right track. It was hoped that the concurrent resolution would pass the House at the present session and that a committee might be appointed to carry on its survey during the summer recess of Congress so as to report early in December.

After reviewing the report on legal work submitted at the 1919 session, this report stated that during the past year a second volume of the medicolegal series on the "Medicolegal Relations of Physicians" had been completed and was now being prepared for publication. This digest contained 3,000 Supreme Court decisions on all the personal legal relations of physicians, except malpractice, and would be of great value to the profession in affording authoritative information on many legal questions of vital importance to physicians. Plans were being made for the compilation of a third volume on the "Powers and Duties of Health Officers" which the growing work of municipal, county, and State health departments had rendered imperative.

In its 1919 report the Council had summarized the history of vital statistics legislation in this country, showing that in 1906 when the committee on legislation took up this work in cooperation with the division of vital statistics of the Bureau of the Census, there were only 10 States in the Union that had any effective laws for registration of deaths, and only 8 in which there was birth registration. A model bill on vital statistics had now been adopted in all but five States, namely, Arizona, Iowa, Nevada, South Dakota, and West Virginia. The house of delegates had reported upon and endorsed a model law and urged its adoption on various State associations. This support had been of the greatest assistance in securing the adoption of these laws in the various States. The Council urged the house of delegates to reaffirm this endorsement and to urge the State medical associations in States that had not adopted it to take the lead in educating public opinion in these States and to secure its adoption at the next session of the legislature. The subcommittee on protection of scientific research had, during the past year, done one of the best pieces of work in its history. Senate bill 1258, introduced by Senator Myer of Montana, while apparently only intended to forbid the use of dogs for experimental purposes in the District of Columbia, was in reality an opening wedge for general restrictive legislation. The bill was referred to the judiciary committee of the Senate and by this committee referred to a subcommittee consisting of Senator Norris of Nebraska, chairman; Senator Colt of Rhode Island, and Senator Ashurst of Arizona. Hearings covering several days were held in Washington during the first week in November, 1919. The usual lobby of antivivisectionists, officers of antivivisection societies, and others was present to urge the passage of the bill. The scientific side of the case was presented by an imposing array of distinguished scientific men under the leadership of Dr. Walter B. Cannon of Harvard Medical School. It was doubtful if any discussion of this question had ever been more brilliantly or convincingly conducted. A full report of the hearing, published by the committee, formed an interesting collection of scientific data as well as an exposition of the misstatements and fallacious arguments of the antivivisectionists. The bill has never been reported out of committee.

Soon after the organization of the original committee on defense of scientific research, a set of rules for the care of animals in scientific laboratories was formulated and printed and copies were distributed to each medical college and scientific laboratory in the country with a request that they be posted and enforced. This voluntary action on the part of the medical profession for the regulation of any possible abuses in animal experimentation had proved one of the strongest arguments against the adoption of special legislation for this purpose. Although the rules were still being enforced, the length of time that had elapsed since their distribution made it advisable, in the opinion of the committee, to print a new edition of the rules and send them to all scientific laboratories. Copies of these rules with circular letter have therefore been sent to each of 85 medical colleges and eleven additional laboratories.

The Committee on Conservation of Vision stated that in addition to 20 pamphlets now on hand, forming a popular series on the conservation of vision, two others were now under consideration, one on crossed eyes and one on cataract. The chairman from this committee and secretary for the Council had conferred with the committee from the American Optical Association with a view to the inauguration of a campaign for the education of the public on conservation of vision especially among school children and industrial employees. This plan if consummated would be financed by the American Optical Company.

The Committee on Cooperation with the National Education Association was reorganized at October meeting of Council. A fourth pamphlet in the series prepared by this committee on the results of health conservation in rural schools was now in course of preparation.

The Committee on Social Insurance appointed by the Council in 1915 reported that the House of Delegates had not as yet seen fit to commit the association to any positive position on this question, evidently feeling that the time had not yet come for the association to go on record either for or against social insurance. The members of House of Delegates, of course understood that the House of Delegates was the only body under the constitution and by-laws of the association, that had any power or authority to adopt any policy or commit the association to any opinion on this or any other question. Its determination lay entirely outside the jurisdiction of the Council. Evidently this fact was not clearly understood by many members, inasmuch as in the last few months statements had appeared in several State journals, either in the editorial column or under the head of correspondence, criticising the Council for failure to take a positive position against social insurance. Such criticism of course was entirely unwarranted, as in was not the function of the Council to formulate the policies of the association. The failure of Davenport bill to pass the New York Legislature left no State in which this question at present was up for discussion in any concerted form, while the growing opposition of physicians and the increasing attention given to it in professional circles would probably prevent the passage of social insurance bills in any State without the medical profession being thoroughly informed and prepared to participate in the discussion of them. The objects which the Council had in view in creating this committee, viz., to arouse the medical profession to a discussion of this subject and to prevent the premature adoption of any such measures in this country, as had been done in England, without full knowledge of the medical profession, had evidently been accomplished.

The Council called attention to the increased registration tax for physicians under the Harrison law which had been increased from one to three dollars. The Council pointed out that this law was enacted by Congress to carry out our international obligations in compliance with the recommendations of Shanghai commission on control of opium traffic, and that it was extremely doubtful whether Congress had any authority under the constitution to regulate importation and sale of drugs so long as the object of regulation was the improvement of public health or the moral status of the people; and that in order to give Congress jurisdiction on this subject, the Harrison law, like the Esch phosphorus bill, had been put in the form of a revenue measure. The American Medical Association and its *Journal* cooperated heartily and cheerfully in the enactment of this measure, in the hope that it would be of material value in restricting the use of narcotic drugs to legitimate purposes. The medical profession of the country also accepted the imposition of the tax and the inconvenience of registration as its contribution to the operation of the law and as necessary accompaniments of any practical plan for control of illicit traffic in habit-forming drugs. The object of the law was not and never had been the raising of revenue. The revenue feature was incidental and secondary, yet in the revenue bill for 1918 the license tax for physicians under Harrison law was increased from one dollar to three dollars. Estimating the number of physicians in the United States at 150,000, this increase formed an unwarranted and inequitable tax on physicians of $300,000 a year. A license law was no more effective with a $3 fee than with a $1 fee. The only possible justification of the Harrison law was the public good; the expense of the operation of the law should therefore be borne by the public and not by a special tax levied on one particular class. The Council recommended that the House of Delegates record its emphatic disapproval of this exploitation of physicians

and that it demand reduction of the registration fee for physicians to a nominal amount and only so long as the law remained in force. The Harrison law had now been in operation a sufficient length of time to afford a fair opportunity of determining its effectiveness. It must be admitted that it had failed of the purpose for which it was enacted, namely, restriction of use of habit-forming drugs to legitimate purposes. It was estimated that there was imported into this country each year four or five times as much opium as was needed for medical purposes. Reports indicated that the efforts to enforce the law in face of this oversupply of drugs had resulted in a marked increase in illicit distribution of opium, morphine, heroine cocaine, and other prohibited drugs, while extortion of the unfortunate victims of drug habits had been made possible by illegal methods under which the traffic was necessarily carried on. Enormous profits of the illegal traffic in drugs had led to systematic efforts to increase the number of prospective customers while the opportunities for profits due to the dishonest enforcement of the law in different localities had led to blackmail and official corruption. Continued failure and scandal could but result so long as it was possible to produce and bring into this country each year many times the amount of these drugs needed for legitimate purposes. The only effective method of control was by Government, through the United States Public Health Service being given complete control of the importation and distribution of habit-forming drugs, the forbidding of their manufacture or importation by any private individual or firm, the ascertaining of the approximate amount needed each year for legitimate purposes, the importation of this amount under Government control and its distribution to properly qualified and registered persons through the Public Health Service, with requirement of strict accountability for all drugs issued. The council recommended that it be instructed to inaugurate an investigation into (1) the amount of narcotic drugs required for each year for legitimate purposes; (2) the amount of narcotic drugs now actually imported into the country, and (3) the devising of effective methods by which these drugs under proper Government supervision might be restricted to legitimate uses.

Report of the Council on Medical Education.—Dr. ARTHUR DEAN BEVAN submitted this report, which stated that instead of 162 medical colleges, which existed in 1904, this country now had but 86, the character of which had been greatly improved. Instead of only 3 per cent in 1904 requiring two or more years of college work for admission now 92 per cent had that standard. The lowest ebb in the enrollment of medical students due to the adoption of higher entrance qualifications was, 13,052 students in 1918-19. An estimate showed that the enrollment in the present session 13,554 students. Increased enrollments of premedical students showed that the classes in medical schools would continue to increase at least during next several years. The trend of medical schools to limit their enrollments of medical students was in the interests of better medical education. Even with this limitation the capacity of Class A medical schools was sufficient to care for many more than were at present enrolled in medical schools and the capacity could be easily expanded to meet future needs. With the higher standards adopted during the last sixteen years, the requirements for admission to medical schools in United States were now on par with other leading countries. The American scheme of premidical education was of particular advantage in that the student could postpone his final selection of the medical profession until he was best qualified to make that choice. Hospital internships were formerly voluntarily obtained by a great majority of medical graduates, but now an internship had been made an essential qualification for license in ten States and it had been adopted as essential for a degree by eleven medical schools. The present demand for hospital internships could not be met if the number of medical school graduates should be doubled or trebled each year, which increase was not necessary to meet the normal demand for physicians. The hospital interne problem might be solved by (1) extending the internship to two years, (2) employing resident physicians, (3) training assistants or nurses to do much of the work now devolving on internes, (4) having stenographers take down histories from dictation at the time the staff members examined patients. There was no scarcity of physicians in United States, but there was an imperfect distribution of the present supply. Medical care in rural communities was improving rapidly with better roads, automobiles, etc., by which the services of physicians in nearby cities might be more readily secured.

A reinspection of all medical colleges was being made by the council preparatory to a revision of the classification of medical schools. This resurvey was also revealing many improvements as compared with conditions found in 1906. The improvement in hospital service was now one of the most important works confronting the medical profession. It was work in which, naturally, physicians were most largely concerned. The American Medical Association also was the agency in the best position to do the work. The work of the association in connection with hospitals had rapidly grown since 1903. Under the Council on Medical Education there was now a bureau on hospitals with a man who devoted his entire time to the work. With the rapidly increased interest in hospital development during the last few years, the work had been correspondingly extended. Besides collecting hospital information each biennium for the American Medical Directory, more elaborate surveys of all hospitals were made in 1912-14 and 1915-16. A third extensive survey was now in progress. An advisory committee on hospitals to cooperate with the Council had been appointed by every State medical society. These committees were doing splendid work and several had undertaken the personal inspection of all hospitals in their States. The association should continue to conduct a clearing house of hospital information; further develop the hospital service department in the *Journal;* perpetuate indexes and classifications; inspect hospitals where satisfactory information was not otherwise obtained; create permanent hospital committees in all States; develop closer relationship with individual hospitals; and cooperate with other agencies working for better hospital service. An organization known as the American Conference on Hospital Service had been created at the suggestion of the Council on Medical Education in which various agencies interested in hospitals were represented. The first meeting was held at the American Medical Association headquarters, Chicago, on April 21, 1919. Subsequent meetings for the completion of organization were held in Cincinnati on September 9-19, 1919, and again in Chicago on March 3-4, 1920.

There was great need in this country of increased and improved facilities for graduate medical education. This need could be best supplied by our leading university medical departments. Efforts should be continued to rearrange educational methods so that the average age of medical graduates might be reduced by at least two years. The solution now seemed to be in reorganization of intermediate and high school education. Extravagant and unnecessary expenditure of money in the development of medical education should be deprecated. In some recent plans for development this point seemed to have been entirely disregarded. There was a serious tendency in present day medical education to drift into the ultrascientific and to ignore or belittle the development of a closer relationship of the preclinical and clinical branches. This tendency would be decreased if it was required that teachers of laboratory departments in medical schools should have had a complete medical training by which they would obtain the medical point of view.

Report of the Council on Scientific Assembly.—Dr. H. SHELTON HORSLEY of Richmond, Va., chairman, reported that the council held a conference on January 10, at which all sections were represented by their secretaries or one or other executive officers. Arrangements were made so that each section would hold one meeting on each of the days assigned for section meetings during the 1920 session. Seven sections convened each morning and eight each afternoon. In the opinion of the council this had made it possible to provide a well balanced scientific program for the entire scientific assembly. At the last annual session of the House of Delegates the section on dermatology requested that

its name be changed to the section on dermatology and syphilology. The council recommended that this request be complied with. The council recommended that the by-laws be amended so that the time allowed for the presentation of papers before the sections be limited to fifteen minutes, and that no one be allowed to discuss a paper more than once or for more than five minutes, except with unanimous consent of those present.

Report of the Committee on Red Cross Medical Work.—Dr. CHARLES W. RICHARDSON reported that the committee having put itself in relation with the American Red Cross, it found the American Red Cross had decided it was useless to call a meeting of the committee or to put it into action this year on account of the cessation of war and that no further need of general action existed between the Red Cross and the American Medical Association. The committee therefore requested that it be discharged.

These reports were referred to the respective reference committees.

Resolutions Opposing Compulsory Health Insurance.—Resolutions were presented stating that the American Medical Association was opposed to any plan embodying a system of compulsory contributory insurance against illness or any other plan of compulsory health insurance which provided that medical service be rendered to contributors or their dependents, provided it was controlled or regulated by any State or Federal Government.

Medical and Surgical History of the War.—A resolution was offered that an appropriation of $150,000 which had been made to the Surgeon General's office by Congress be used in the preparation of a medical and surgical history of the war.

Second Day—Tuesday, April 27.

Report of the Reference Committee.—The Reference Committee, to which had been submitted the various reports made on Monday, recommended as follows:

Report of Judicial Council: The committee submitted the revised constitution and by-laws to the House. The changes in the same were taken up, discussed, and voted on seriatim, and the revised constitution and by-laws were adopted by the House as a whole.

Legislation and Public Relations, Report of the Council on Health and Public Instruction, and that of the Special Committee on the Narcotic Drug Situation: The Reference Committee reported that it had considered the reports of both 1919 and 1920 and commended the progressive spirit of the Council in dealing with these many problems of vital importance to the medical profession. It recommended that the House of Delegates endorse and approve of the Senate concurrent resolution providing for a joint congressional committee to make a survey and report on Federal public health activities, and that it urge its passage by the House of Representatives. Such survey would furnish information needed and would mark another step forward in securing national health organization. The committee approved of the medicolegal work which had been carried on and recommended that the Council be instructed to complete this work. The work of the Council in securing the passage of a model bill for registration of deaths and births was approved and the Council was instructed to urge the medical societies in States now without adequate laws on this subject to take the lead at the next legislature in their States to have this bill enacted. The work of the Committee of Scientific Research was approved, and it was recommended that a report of the hearings before the Senate committee on antivivisection be reprinted as one of its educational pamphlets. It also offered the recommendation that the State associations have committees appointed to attend the State Teachers' Associations and to ask the appointment of a committee from the Teachers' Association in each State to cooperate with the medical profession to promote health in the public schools. The committee recommended that the House record its disapproval of the inequitable increase in the cost of registration of physicians under the Harrison law and demand a reduction of the fee to a nominal amount so long as this law should remain in force. The only effective solution of the narcotic drug question was for the Federal Government to take complete control of the importation of habit-forming drugs, restrict the importation to an amount required for legitimate purposes, and provide for the distribution through the Public Health Service of such drugs to properly qualified and responsible persons only. It recommended that the Council on Health and Public Instruction be directed to inaugurate a systematic survey and then to report on the amount of narcotic drugs required each year for legitimate purposes, and on the methods by which these drugs might be restricted to legitimate purposes. It also urged that other recommendations be adopted as follows: That ambulatory treatment of drug addicts so far as it related to prescribing and dispensing of narcotic drugs to addicts for self-administration at their convenience be emphatically condemned. That heroine be eliminated from all medical preparations and that it should not be prescribed or dispensed, that the importation, manufacture, and sale of heroine should be prohibited in the United States. That Senator France's bill 2785 and Representative Rainey's bill 11778 to provide aid from the United States to several States in the prevention and control of narcotic drug addiction and in the care and treatment of drug addicts be approved, and that Senator France and Representative Rainey be so notified. In view of a statement in the Government report that about 90 per cent. of all narcotic drugs now imported were used for other than medical purposes, the Treasury Department was respectfully urged to study and report on the narcotic drug situation, including the question of Government control of these drugs; and that the Bureau of Public Health of the Treasury Department be respectfully requested to continue the compilation of State laws and regulations relating to habit forming drugs and bring it up to date. The committee recommended the adoption of the report as a whole and urged the Association to lend encouragement and assistance to the Council in order that the work might be continued.

Health Insurance: The Reference Committee had carefully considered the resolutions on health insurance, as amended, and recommended their adoption. It also offered a resolution that the Council on Health and Public Instruction be instructed to investigate and make a survey regarding the adequacy of medical service to the public, and to report at next meeting. All the resolutions presented by the Reference Committee were adopted.

OPENING MEETING.

Tuesday Evening, April 26, 1920.

DR. ALEXANDER LAMBERT OF NEW YORK, PRESIDENT, IN THE CHAIR.

THE meeting, which was held in the Shriners' Temple, was called to order by the president, Prayer was offered by Bishop Laval.

Addresses of Welcome.—Owing to the unavoidable absence of Mayor Behrman, the Hon. Mr. Riggs extended the welcome of city to the association. The medical profession of Louisiana extended a warm welcome through Dr. Homer Dupuy, president of the Louisiana State Medical Society. On behalf of the people of the State, Governor Elect John M. Parker extended a cordial welcome. In his address he expressed his appreciation of the honorable privilege which was his of addressing such an intelligent and patriotic body as the American Medical Association. He appeared before this body feeling better than he had at any time since his nomination for governor, owing to the fact that for the first time in the history of Louisiana arrangements had been made for properly taking care of the insane, feebleminded, defectives, and other persons needing hospital and institutional care. Within the last few years, in traveling over the State, he had been impressed with the lack of proper facilities for caring for these individuals, and had determined that during his incumbency no politics should enter directly or indirectly into the management of institutions for the treatment and care of these unfortunates, who formed a considerably increasing element of the community. He asked that distinguished and experienced alienists suggest the names of young physicians who would be able and willing to make a special study to

fit themselves for manning these institutions, so that their management might in time be in the hands of men absolutely free from political influence, and capable of giving the very best service. The great medical centers of the East could be of invaluable assistance to the South in this regard. What was needed, not only in Louisiana but in other southern States, was a radical commonsense change in the management of these public institutions. In this work he earnestly bespoke the cooperation and assistance of the American Medical Association.

Introduction of the Incoming President.—Dr. ALEXANDER LAMBERT, the retiring president, in introducing and installing the president elect, Surgeon General William C. Braisted, U. S. Navy, paid a glowing tribute to the Navy, which had always been held high in esteem by the American people. The association had expressed this appreciation by making the surgeon general of the Navy its president.

Address of the President.*

Rear Admiral W. C. BRAISTED, Surgeon General, U. S. Navy, then delivered the Presidential Address, in which he discussed "The Obligations of Medicine in Relation to General Education." In the old Navy, he said, a midshipman was defined as a person with no rights and few privileges, and many societies and associations had a feeling akin to this about their president and regarded him as a sort of lay figure on which to drape honors but from whom no serious participation in affairs was expected. He hoped no one would think he was exceeding his rights or straining his privileges in taking for discussion a subject which had been largely entrusted, during the Association's long campaign for the education of the public and the improvement of our medical schools, to members having special knowledge and special ability. He believed that, while leadership belonged to the few who enjoyed peculiar qualifications, intelligent cooperation was the obligation of all, and he therefore conceived it his part to foster by every means in his power a general participation in the educational program which had characterized this Association since its incipiency. He then continued:

It is glorious to think that the practical, material benefit which we anticipate from this meeting is only secondarily for ourselves. We want to be more capable in the service we render to our patients rather than to increase either fame or fortune. This is very well as far as it goes, but it is not enough. We must realize afresh at each annual convocation that before being members of the Association we are physicians, before physicians citizens, before citizens men. In so far as we neglect the functions of the citizen or forget the obligations created by man's social environment and repudiate every duty not directly connected with private practice, we are recreant to a high trust.

In the recent war the medical men of America laid aside their practices at no small sacrifice and with no small risk to their future prospects to play the patriot; and so did lawyers, business men, teachers in colleges, scientific investigators, and so on. It was a noble stand to take, but the glory of this spontaneous uncalculating action will be considerably dimmed if, now that the threat of invasion, the foreign menace to our institutions has passed, we relapse into that narrow life pursued by so many who tacitly maintain that because they sustain important private relations to the sick they are absolved from participation in the struggle for the betterment of town, city, county, State and country, and of the world itself.

In this matter of responsibility outside of mere professional life we all need education and what more fitting opportunity than this to solicit from you all a holier dedication to your patients' interests by thinking of what they need to be told, how they should be guided and how helped when they are not actually suffering from bodily ailments. When we do this we are at the threshold of social and preventive medicine —a medicine of education as well as of prescribing and operating.

*An abstract from advance proofs through the courtesy of the Editor of the *Journal of the American Medical Association.*

Education of the Public in Health Matters.—The education of the general public in matters relating to health has not been entirely overlooked in the United States. A good deal has been done, especially in the last few years, but the sum total is small indeed when considered, on the one hand, in relation to the importance of the subject, and, on the other, to our great territory, huge population, vast resources, multiplied and highly productive forms of energy and our general advance along all lines. Certainly in many details of health regulation and health promotion we are behind the older nations of Europe, relatively if not absolutely. After the dissipation of life incident to all great wars, men invariably turn to the importance of saving life and prolonging it, and health-giving measures excite at least a temporary interest. We will therefore miss a great opportunity if we do not at this time use every endeavor to press home the great self-evident truths about health and long life as they affect national prosperity and race permanence.

Is there anyone who doubts for a moment that the physical integrity of its citizens and their ability to deploy all the energy which unvitiated, untainted nature can generate are of the first importance for the onward and upward progress of this republic? Is the health of the nation a national concern? If so, then the nation as such should go into the matter with the same business acumen, on the same scale and with the same continuity of effort manifested in any other vital public concern.

One of the most remarkable and anomalous incidents of history is the way the Hebrews have preserved their race entity and characteristics though deprived for two thousand years of a local habitation and though prior to their final dispersion they had been for centuries the objects of foreign domination—enslaved, driven out, carried into captivity. While today the Jews may enjoy the benefits of other civilizations than their own, it is generally recognized that in the earlier periods of their history their cohesion and their national achievements were largely the result of a unique and remarkably extensive hygienic and sanitary system far beyond anything employed by any other race. Their peculiar observances were not due to the influence of physicians, to whom there is scant and none too favorable reference in the Old Testament, but embodied the wisdom of Egypt and Mesopotamia and had behind them the force of civic and religious obligation and were administered by the priestly caste.

The State's Need of Sturdy Men.—Can we pretend for a moment that the stability of Rome through twelve centuries of existence under kingly, republican, and imperial rule, vexed by enemies within and without, was not dependent in a large degree on the extensive municipal provisions for health, which included an ample and excellent water supply, adequate drainage, extramural sepulture, and on the universal respect for physical prowess and physical hardihood inculcated by kings and consuls and not by the physicians, who to their lasting shame cared little for these things? We know how much the national life of Sparta owed to its rigid discipline and the paramount emphasis laid on bodily vigor, and how Athens all through its glorious period of intellectual development continued to cultivate physical perfection. To my mind the most paradoxical feature of our modern civilization is the indifference of a comparatively educated and well informed world to the human body. I submit that the nation's health is a national concern; that it underlies all industrial and business effort; that it is the fundamental element in successful competition with rival nations, whether under the slow and prolonged strain of commercial contests or the sudden and imperious demands of armed conflict; that if we look ahead, as true love of country compels us to do, and estimate the trend of future events, we must acknowledge that physical vigor will, in a large measure, decide our complete development and permanent possession of the land which our forefathers won for us not only on the fields of battle but in strenuous struggles against the elements; in the mighty labor of felling forests, tilling the soil, and developing the resources hidden in the heart of the earth.

I am very far from undervaluing the work of the

many agencies already engaged in indoctrinating the people in the fundamentals of health; but it is undeniable that so far their efforts have been inadequate to the magnitude of the task as I conceive it. The campaign must be one of concerted measures, nation-wide in extent and unflaggingly prosecuted.

Teaching of Hygiene in Primary Schools.—I think that up to the present we have been guilty of a cardinal error in seeking wholly to proselyte the adult. Our preaching has been to people enslaved by the chains of lifelong habits. We have advised men with damaged hearts and kidneys and blood vessels to eat and drink and smoke less; to take moderate exercise; to learn to relax and play; to avoid undue excitement so that they might spin out the thread of life by a few years. We have appealed to high school, college, and university students to abjure tobacco and alcohol; have held up personal purity as something of supreme importance, given instruction about venereal diseases, instituted courses in personal hygiene that perhaps conveyed to them for the first time in their lives some rudimentary knowledge of their own bodies. In all this we have overlooked two things. The man of middle life cannot make his depraved body over and replace worn out organs. If he stops work he dies for lack of occupation. If he gives up some habit that has become an integral part of his being he may suffer devitalizing mental and bodily reactions not unlike those of the opium eater deprived of his drug. The lad or maiden who has for years been goaded to study grammar, mathematics, languages; on whom there has been exerted insistent pressure to acquire mental attainments, cannot easily be persuaded later on that a subject kept in the background or displaced in favor of something else is the one of paramount importance. We cannot expect the young to believe that hygiene, physiology, and health are matters of prime importance when everything else has come ahead of these subjects. The children are right, because we do put first what we esteem to be first. I propose that we abandon at once all half measures, get away from routine, conventional methods and embark on something new, radical, revolutionary, but something at the same time perfectly feasible, if undertaken on a scale fully commensurate with the colossal results desired.

Sound Health the First Requisite of a Liberal Education.—Let us throw out as irrelevant and misleading the occasional benefits conferred on humanity by the prodigious accomplishments of some individual whose genius bordered on insanity; let us forget that here and there an invalid, a neurasthenic, a neurotic has enriched the intellectual life of the world or done some epoch-making thing. Let us begin the child's education by teaching him health before everything else; first in point of time, first in importance. We must get possession of the child himself, affect his inner consciousness, modify his personality, and give his life a definite bent, so that he will progressively and increasingly contribute by his own efforts to secure and preserve the health indispensable for the fullest use of the opportunities of high school, college, and university. The primary school is universally recognized as the place to acquire certain things indispensable to future mental development and ultimate success. There is world unanimity about these essentials, but how common it is to have to take children out of school for reasons of health before they have got well into the three r's—reading, writing, and arithmetic. What I propose is to go back of the three r's and begin all education by instilling into the child before he can read or write some knowledge of the human machine and the laws that regulate its upkeep; to elaborate and intensify this teaching step by step with other instruction, showing by practical illustration how to obtain the maximum yield from this machine. The teaching of physiology and hygiene to the youngest pupils requires no book, but it does require a trained teacher. Unfortunately, however, there are teachers who do not care for that feature of the work even though they are competent. The reason for their indifference to the subject is that they did not grow up in that atmosphere of health culture which I would like to see created for the next generation. The really clever teacher makes his subject entertaining and interesting but does not wander far afield in search of mere diversion. The teaching of health and the first anatomy and physiology lessons will be by the Socratic method of question and answer, and by the still older case-method first known as the parable. There will be no fear of lack of interest when the day's session begins with a tale like this. "John ran away from his mother. He was so little and he ran so fast that he fell down. There was a piece of glass just where he fell and he struck the sharp edge of it with his hand. What happened? What made the blood come? What is blood? Do animals have blood? What is it for? How was the bleeding stopped?" Such lessons can be varied and multiplied indefinitely and made practical by reference to or, when possible, by actual demonstration with natural objects and natural phenomena.

They are very much mistaken who tell you that children cannot think and would have early instruction rely in the main on memory. Even very young children do far more thinking and think far more accurately than the average adult realizes. They are not capable of abstract thought, but in relation to the things of everyday life they are constantly observing and trying to deduce conclusions.

The child is forever discovering new and surprising aspects of his terrestrial environment and is eager to investigate them. He gets into many a scrape through ceaseless experiment with cause and effect. He is eternally asking, "Why?" What a field is this young mind for the sowing of seed, and how much needless suffering and disappointment he can be spared if we will only teach him the important things first.

In the kindergarten and in the lower grades of the primary school which are to be devoted, in the proposed scheme, to health and hygiene, clean hands, clean finger nails, clean faces, proper carriage, proper breathing; sound, well-brushed teeth, and all the little details of physical deportment that are matters both of social convention and of health (like the use of a handkerchief for a moist nostril, holding up the hand to cover the sneeze or cough) will receive reward and make for class standing exactly as does the correct solution of an algebra problem or a good recitation in the higher grades. As the pupil grows and advances the health instruction will be increased and extended, and will, I am sure, serve to make chemistry, physics and natural history more interesting in themselves, while, conversely, these topics will render more intelligible the hygienic lessons.

Public Schools as Natural Health Centers.—Our public schools, then, must become the health centers of their respective communities. Every measure carried out in them should be fully explained, so that the wisdom of preventive measures shall be fully appreciated by the pupil and he may become an advocate of them for the rest of his life. In connection with the bowl of hot broth furnished daily there may be lessons in diet. Temperance in all details of food and drink may be inculcated at the same time that the evils of alcohol, tobacco, and narcotic drugs are set forth. Then the necessity for scalding knives, forks, and spoons must be emphasized and the menace of the mouth secretions fully explained. The child must acquire, on the grounds of health, the same horror of the mouth secretions that refined people have for the spitting habit. Such a program may commend itself to you, but the difficulties attending its execution are rather staggering. In the first place, we must have better teachers, and that means teachers who have had special training and will therefore expect better pay. There will be need for special textbooks, and this is one of the most critical features of the whole business, for good books of any kind for children's use, and especially textbooks, are among the hardest things in the world to produce.

While on the subject of schoolbooks, and having in mind the examinations conducted under the draft law, which revealed a high percentage of refractive errors in our adult population, I cannot refrain from making something more than a passing comment on the type used in the schoolbooks supplied to young children. Some thought has been given to schoolroom illumination and to proper posture in reading, but nine children out of ten, if left to themselves, get their noses on the paper when they write; hold the book too close when they read, and will do both without regard to the quantity or source or direction of the light. Dr. G. I. Hogue, in an address before the school teachers of Milwaukee,

estimated that 30 per cent. of the schoolchildren of this country had some visual defect. In Milwaukee, 27.24 per cent. of the schoolchildren had visual defects. In New York City, out of 650,000 children in the public schools, 30 per cent. at least were two grades behind what they should have attained. Ninety per cent. of these backward pupils are suffering from some defect in eye, ear, nose or throat. He estimates that out of 22,000,000 schoolchildren in the United States some 6,000,000 suffer from ocular trouble. Good food, ample exercise in the fresh air, and hygienic surroundings will counterbalance a host of objectionable practices, but the ever-growing strain imposed on the human eye by modern life calls for special consideration. I profess no special knowledge of the pathology of the eye, and I have consulted no specialist preliminary to making these remarks, but I do not hesitate to declare that the time is ripe for a reform in the construction of children's schoolbooks.

Causes of Eyestrain in Children.—When you get home from this meeting take your child's geography, history or arithmetic—if not blessed with a child of your own, a nephew, a niece, a neighbor's or a patient's child can supply you—and observe what a large proportion of the text is in fine print. The paper is good; the illustrations are attractive, and the binding is child-proof, but the questions for review, the footnotes, and much of the explanatory matter are set up in six point. I think I am very conservative in the opinion that no child of 10 or under should have to study a book printed in anything smaller than twelve point lower case or eight point capitals, and older children should not have to con by the hour a type finer than ten point. If fine print could be officially stigmatized as a menace to eyesight; if the federal government were to forbid the transmission through the mails of children's schoolbooks improperly printed, we would have a ready solution of the problem. Left to the example of the individual school or to the individual State, the correction of an evil of this kind will not be achieved for many, many years.

This thought and a consideration of the difficulty of securing the services of properly trained teachers and sanitary inspectors and physicians not merely for local experiment, for the collection of data, as a demonstration of some useful doctrine, but as part of a continuous and permanent health campaign, lead naturally to a consideration of government responsibility for the public health fostered and encouraged in the children but affecting also the adult in relation to trade and commerce, preparation for war and so on.

Need of a Federal Department of Health.—I wish that the public had a fuller appreciation of the really great educational work of our distinctly military services. Through the work of the medical officers of the Army and Navy, our government may be said to have been carrying on for years a health propaganda, within the sphere of the activities presided over by two cabinet officers, affecting directly some 200,000 men in time of peace, and, to a much more limited extent of course, in the past three years acting on a force of several million men. But if we continued to maintain an army of from two to three hundred thousand men and a navy of a hundred thousand the matters of health which are made prominent in military service would still not directly touch half of 1 per cent. of our population, and we have these men under our influence for relatively short periods—not more than from four to eight years out of a life of three score. This humanitarian, educational work is an incident and not the chief purpose of the departments referred to.

We have to admit, then, that vital as it is for us to maintain a high standard of physical development for the eventualities of war, neither the Secretary of War nor the Secretary of the Navy has any way of concerting measures which will assure for the military needs of the country the necessary number of men of sound bodies with unimpaired special senses. We reject every year thousands of applicants for enlistment who are ineligible for service by reason of conditions which might be regarded as preventable but which are not prevented. We reject men with serious defects of the teeth, with inferior vision or color perception, insufficient development of muscle, bone and tendon, poor heart-action and a defective innervation. Furthermore, the conditions of life in this hurried age; the social environment of the tenement; insufficient training in the home or the lack of a home, and the ravages of alcohol and syphilis in parents, are making for the development of neurotic and unstable types unavailable for service training in peace and of worse than no value for war. All these men are debarred at the recruiting office, but what becomes of them? The Secretary of War and the Secretary of the Navy have no cognizance of them, but they remain a part of the nation, an element of weakness, a burden, a disgrace and transmit their defects and weakness to their children. The bad teeth, the weak, strained eyes, the overworked, injudiciously used hearts, and the distorted and depraved nervous systems are all preventable. Whose care is it to concert far-reaching plans to fend off from the younger generation and future generations ills that are not by any means an inevitable concomitant of birth?

It is by what might be called an accident of birth that our very efficient but small Public Health Service is conducted by the Treasury Department. The U. S. Public Health Service, originally called the U. S. Marine Hospital Service, dates from 1798, when Congress made provision for the medical care of sailors in our merchant marine by generously mulcting each sailor 20 cents of his monthly pay for the support of hospitals ashore and for the pay of the physicians who worked in them. The money was to be collected by the several collectors of customs, who were of course officials of the Treasury Department. It was not until nearly a hundred years later that this body of physicians had any but a curative function.

In 1878 Congress directed the supervising surgeon to prepare and forward to State and municipal health authorities weekly abstracts of consular reports and other information relating to contagious and epidemic diseases; but it is interesting to note that even in 1796 Congress had recognized some measure of responsibility for public health by passing an act requiring all revenue officers to cooperate in the execution of state health laws.

In 1879 Congress appropriated $50,000 for a National Board of Health whose existence was limited to a period of four years. This board owed its creation to the terrible epidemic of yellow fever raging in the Mississippi Valley. It was after this that the Marine Hospital Service was financed by funds voted by Congress for the specific purpose of preventing the spread of epidemic disease, more particularly smallpox and yellow fever.

In 1892 the Marine Hospital Service achieved notable results in preventing the introduction into this country of the cholera so extensively prevalent in Europe. Then came the passage of an interstate quarantine law and later a national quarantine act in virtue of which a systematic examination of all immigrants has since been maintained. Gradually this service has assumed a distinctly educational function. Its Research Laboratory was one of the first agencies of the kind. Its work in connection with malaria, pellagra, hookworm, infantile paralysis, leprosy, rabies, typhoid and Rocky Mountain fever, school hygiene, the pollution of water, trachoma, the problems of rural life, and railroad and industrial sanitation, has been of a high order.

I give this outline of the history of the United States Public Health Service because I think too little is known of what it has accomplished; because its growth in importance shows very plainly that, as the value of this kind of work became more and more apparent, ways and means were found to make it possible. The work has been economically done by trained experts often opposed by local prejudice but far more seriously hampered by general indifference and by the fact that they could act only in an advisory capacity, and were only a side issue in the Treasury Department, whose main concern was with other and very unrelated affairs. This history of the Public Health Service illustrates how the government has been able to play a rôle of considerable importance in promoting public health though acting in an ancillary capacity, and we see how from purely medical practice its members have assumed more and more an educational function. Then, too, in recent years the government's obligations

have been recognized by the passage of pure-food and child-labor laws; by enactments regarding the sale of narcotic drugs; by assigning to the Public Health Service supervision of the manufacture and sale of serums and vaccines. But to-day the public health is, so far as the federal government is concerned, a matter of secondary importance whereas it should be first.

Wastage of Life and Natural Resources.—As a people we are of all civilized nations the most wasteful of human life as well as of food, natural resources and public funds. France and Italy have a minister of public education and England has a ministry of health. During the year 1917 our railroads, which under government administration cost us a million dollars a day, were responsible for 194,000 injuries, 6,300 of which resulted in more or less serious crippling, and for 10,000 deaths. In the same year the funds assigned for the maintenance of the United States Public Health Service, including its laboratory, its department of zoology, its field work, the salaries of 200 medical officers and 1,800 other employees totaled $3,250,000. That is to say, the national government's expenditure for its only accredited and official agency for the care of the national health was at the rate of a little over three cents a head for the total population. As regards vital statistics, birth registration and morbidity reports we are far behind Europe.

A department of health in Washington would be purely civilian in composition and would call to its aid or give its assistance to all private or corporate forms of endeavor, very much as the army and navy call on the Carnegie Foundation, the Rockefeller Institute or the American Red Cross. Then we would coordinate effort for improved public health of every kind and make it continuous and progressive instead of desultory and sporadic, and many problems would be diligently attacked which now, in spite of their importance, must await until some great calamity excites public attention or arouses the sympathy of a philanthropist.

Facts Revealed by the Operation of the Draft Law.—We have learned and the general public has learned a good deal about our national weakness from the facts revealed by the operations of the draft law. Massachusetts, stimulated by the knowledge of the number and character of the rejections for military service, and other sections of the country alive to the declining birth rate of the white race are proposing enactments to remedy crying evils in the physical development of our people, but years may pass before other sections awake to the importance of these efforts. Meanwhile the whole nation is concerned and the nation as a whole should be at work to remedy what is wrong.

How are we to explain the fact that the older sections such as New England, New York, Virginia, North Carolina, and Louisiana lead in nervous and mental disorders; that in defects of the eye New York, Boston, and New England generally and the cities of Ohio, Michigan, and Illinois were the most conspicuous; that Rhode Island led in defect rate and Vermont came next, while Kansas had the lowest defect rate of all the states; that the extreme northeast, including New York and New Jersey made the poorest showing in regard to the teeth? Are these fortuitous facts or are they susceptible of explanation and correction? It is clear that when we have as physicians informed ourselves on these topics there must be education of the public to prepare it to cooperate with, and there must be legislation to enforce, the necessary corrective measures. There is a mystery in the report of the Provost Marshal General that Oklahoma and Arkansas for the number of men examined gave the highest percentage of men going into Class A and Arizona and Rhode Island the lowest—men in Class A being the fully qualified, able to see and hear well, able to transport themselves by walking, having a circulatory apparatus able to stand the stress of physical exertion, the intelligence to understand and execute military maneuvers, obey commands and protect themselves.

Nation-Wide Versus State Control of Health Matters.—How impractical to expect that any one State alone, or even two or three, should go into the study of these things at considerable expense, or that just and reliable conclusions could be arrived at from such a partial study! These are national matters most easily, most economically and most satisfactorily studied as national questions by national rather than local agencies. I can perfectly understand a strong disinclination to any step that might appear to open the way for government control or restriction of the practice of medicine or that tender to paternalism, especially in view of the agitation developing here and there for all sorts of medical, dispensary, and hospital privileges. As a general proposition, I am firmly opposed to the disposition to saddle every public and semipublic enterprise on the government, but I am unqualifiedly in favor of a national department of health with a cabinet officer at its head which shall by its very creation give a great object lesson to our people and shall correlate and vastly expand all the efforts now put forth for the improvement of the race, the prolonging of life and the full development of physical capacity for work and production.

Practical Knowledge of Hygiene Needed by Physicians.—Our semiscientific and popular current literature, and even the daily papers, are constantly giving out bits of information about the flea, the louse, the bedbug, and the mosquito in their relation to the transmission of disease. A layman does not quiz his physician about anatomy or pathology, but he does turn to him for enlightenment about these and kindred matters bearing on health and disease which he can understand and on which he would like to be informed. When the physician cannot fully satisfy the questioner about the rôle of these insects, about the potability of water; the danger of damp, newly constructed buildings; the proper trap to a water closet; the infections that may be acquired from intimate contact with domestic animals, he loses enormously in prestige and, what is more important, he loses the chance to thrust home some valuable lesson in public health and public duty.

We are beginning to develop here and there schools offering special courses and special degrees in hygiene, and I think this is a forward step, for we must have men of special training prepared to do advanced research work in this field, but can any one reasonably pretend that the medical profession can wisely permit this branch to become one for specialists only, and that, while pathology belongs to the physician, hygiene and sanitation are not his sphere? On the contrary, will not the exhaustive teaching of hygiene and of public health medicine in our medical schools immeasurably enlarge the scope and improve the character of the practice of medicine itself?

Let us institute a thorough course in hygiene and sanitation, making a real knowledge of the subject indispensable for graduation. We could include in this course whatever features of the specialties bear directly on the public health.

Restrictions as Applied to Candidates for Admission to Medical Schools.—Far more important than determining what particular subjects are to be emphasized and how the medical student's time is to be apportioned in classroom and laboratory is the standard of fitness to which a young man must conform before he can be permitted to study medicine. Admission to a medical school contains the implied promise that diligent application for a given period will qualify him for a diploma as a doctor of medicine. In justice to the public, to the profession, and to the candidate we must endeavor to establish three things before the medical school opens its doors to him. The prospective physician must be sound in body; he must have sufficient mental training and acquirements to enable him to pursue the course with profit; he must give evidence of those personal, temperamental, and moral qualities which promise reasonable adaptation to the highest aims and purposes and to the best practice of the American profession.

There is, I am convinced, a real danger in the modern trend to practical instruction so called. The danger of neglecting the necessary fundamental and more or less abstract teaching for the distinctly enjoyable clinical and bedside work is increased by the realization that the latter has stronger attractions for the student and that it greatly facilitates the acquisition and retention of information furnished in the classroom. Students and even teachers speak of schools as theoretical

and practical, having in mind apparently the distinction between didactic lectures and laboratory exercises, but it is very easy for an unconscious transposition of ideas to lead one to think of theoretical instruction as removed from the domain of usefulness to the sick because the word theoretical is connected with the idea of speculation and hypothesis. Now, as a matter of fact, by theoretical instruction in medicine we mean the abstract handling and presentation of scientific truth as compared with its application as a practical means of healing. With this clarification of terms it becomes manifest at once that the school must be primarily the place for medicine as a science, for if the young physician have not scientific knowledge what is he to apply when he comes to the bedside?

Eras of Medical Teaching.—We have known in this country the era of strictly practical medical teaching. The physician jogged along from house to house, and the neophyte who accompanied him saw the patients and picked up what he could about them through the dissertations of the preceptor. It was followed by the era of cheap medical schools where men were shown at clinics the manifestations of disease; where they committed to memory prescriptions for fever or diarrhea or cough. These schools had short courses and the fees for diplomas were essential to their maintenance. We have, through the American Medical Association, rung the death knell of the medical diploma mill. But historical justice compels us to admit that there was much excuse, in our country's undeveloped period, for giving some kind of brevet to men willing to settle and supply what primitive rude aid they could in remote and sparsely settled sections that would never have attracted or adequately compensated those who had spent the time and money necessary for more complete training in the half a dozen high-grade medical schools we possessed. Conditions are very different now, and there is a more equal distribution of wealth and education throughout the land; the standards and requirements of various geographic sections are more uniform. I look forward to the time when we shall have in this country an even higher standard than now and uniform medical requirements with comprehensive courses of five and six years as in England, France and Italy. That a need for something of this kind has been recognized by the profession in this country is shown by the rise of the American College of Surgeons and other American colleges, to be a fellow of which implies an advance in attainments beyond those of the ordinary graduate. This need is shown, too, by the existence to-day of the National Board of Medical Examiners, an incorporated but privately supported organization whose aim is to stamp the successful candidates coming before it as men of peculiarly liberal acquirements. The gradual elevation of State requirements for license to practise and their constant approach to uniformity justify this board in looking forward to a time in the near future when we shall have a single standard for the whole country.

Galen in trying to stabilize medicine, to free it from wild speculation and the vagaries of individual schools and the excesses of individual teachers bound it with iron bands and stopped all progress for thirteen hundred years. The Faculty of Paris, standing like a rock for a maximum of book learning, insisting that the physician must be a savant, holding to narrow conceptions of the dignity of the profession, despised the manual operations of surgery, exacted from aspirants for a license an oath to do no surgery and by cutting itself off from the opportunities for acquiring that knowledge of anatomy, physiology, and pathology afforded by operative investigation made the practice of medicine in France as dead and as meaningless as the branch which it so effectively circumscribed for four centuries. But just here is a feature of the development of medicine that we are apt to overlook. It was not until the itinerant bone setters, the cutters for stone, the oculist, the herniotomists succeeded in being admitted to the schools that they exercised any vital effect on the profession. The schoolmen were narrow, as every one admits, but the practical men who had not been to school were butchers, and they had no real influence until surgery in the person of Felix cured Louis XIV of a fistula in ano which had never been benefited by salve or unguent. Maréschal, successor of Felix as court surgeon, influenced Louis XV to establish five chairs of surgical instruction and La Peyronie induced him to pass an ordinance making it obligatory for masters of surgery to qualify first as masters of art.

The Evils of Too Purely Academic Instruction.—In recent years we have perceived with ever increasing intensity the evils of a too purely academic instruction, and in the inevitable reaction to practical methods we run the risk of going to an equally dangerous extreme the other way. It behooves us to find a way to teach so that the two lines shall have their proper proportion. All ages, whatever the attainments of science, have produced great healers, and the family physician of an earlier generation must ever remain the ideal minister to the sick. It is the personality of the upright, big-hearted man whom people trust to use what knowledge he possesses rather than abstract scientific qualifications that counts in the long run. Can we expect men to qualify for the sacred function of receiving the confidences of sufferers in mind and body if we expunge poetry and philosophy and art from their preliminary education and wholly replace fairy tale and legend, Longfellow, Tennyson, Hawthorne, and Shakespeare by so-called strictly scientific premedical work? We want a man broad in interests and understanding, not the recluse who finds more pleasure in dissecting a beetle than in viewing a sunset, who gets more soul satisfaction out of the hum of a machine just because it is a machine than in listening to a Patti singing the Last Rose of Summer. Dr. W. M. Beach of Pittsburgh well epitomized all this when he said at Atlantic City last year that "proficiency in the physician requires development in the direction of spirituality; there is a curative force that is moral."

The Kind of Men Needed.—We want the men who take up medicine in America to be big men; big in heart, big in brain, blessed with vigorous health. The possession of a store of facts is nothing as compared with evidence of native ability and sterling integrity of character. Before we permit a young man to matriculate in medicine we should have assurance that he is careful of his health and careful of his financial obligations; that he commands the respect of former classmates; that he has qualities that make for leadership; above all else that he understands and justly values and possesses that indefinable exquisite, delicate something as intangible but as real as the bloom on the plum and the fragrance of a wild flower—the sense of honor. Our inquiry into the premedical career of a prospective physician will be of infinitely more value if it enlightens us on these points than if it merely establishes his ability to memorize a book and on admission we discover that the high marks and the multiplicity of diplomas were won by a physical and moral runt.

It is time that the subject of examinations be very thoroughly gone over by professional educators and substitutes found for such methods of testing a candidate for promotion or honors as do not indicate reasonably lasting acquisition. The bulk of our examinations as at present conducted have but little to recommend them. Their only merit and the reason why the pedagogic world hesitates to discard them lie in the powerful stimulus they provide to the study of even the most difficult branches and the most obnoxious details. When, however, we stop to consider that the labor incited by the examinations is usually not for the acquisition of knowledge but for the passing of the examination; when we admit that the modern examination determines, in the main, a very ephemeral form of attainment, we may find that something better than the examination may not be so very difficult of accomplishment after all.

Present Methods of Examination.—The present method is vicious for two reasons: first, it fails largely of its object because we do not get a correct idea of mental capacity and mental development, nor a proper appreciation of a student's grasp of the subject by examinations which he can undergo successfully by cramming. In the second place cramming is a devitalizing process and the very opposite of memory cultivation, because behind the effort to acquire is the deliberate conscious purpose of unloading the mind of the stores taken aboard as soon as a given contingency has

passed. The willingness to forget and the deliberate effort to forget negative and weaken the retentive power. For years, in our examinations at the Naval Medical School in Washington, we have allowed laboratory notes to be used by candidates in the chemistry and hygiene laboratories considering that memory for the exact quantities in various solutions is not required, nay undesirable, where men are trying to do accurate work. What we demand are the principles involved, the meaning of the steps, the interpretation of the results. This is the method followed by the National Board of Medical Examiners. It is in the necropsy room, the laboratory and the hospital ward that we test the candidates in an endeavor to ascertain what they know by what they do, instead of judging entirely by what they say or write.

Basis for Scientific Study.—Sir George Makins, president of the Royal College of Physicians, does not think that we should relegate the teaching of physics, chemistry, and biology to the premedical period for fear that the medical student may not have a sufficiently thorough grasp of these subjects. On the other hand, Thomas Huxley held very emphatically to an opposite opinion. He said: "The great step toward a thorough medical education is to insist on the teaching of the elements of the physical sciences in all schools, so that medical students shall not go up to the medical colleges utterly ignorant of that with which they have to deal; to insist on the elements of chemistry and the elements of physics being taught in our ordinary and common schools so that there shall be some preparation for the discipline of the medical colleges."

I agree with both Makins and Huxley. My own view is that these subjects should be taught in the school and college course and in the medical school also. In the preliminary courses pupils should acquire a knowledge of the great fundamental principles involved and the methods employed in scientific work, because all this emphasizes the value of accurate observation and correct interpretation of facts and both of these mental processes are invaluable in every department of human activity. The future lawyer, doctor, business man needs this training. In the medical school chemistry, physiology and biology will be taught with reference to their bearing on medicine. But the premedical courses must be very different from those now pursued. The textbooks must be simpler and the courses be made general and then pupils must be compelled to master what they go over. I should put biology and physiology or nature lessons among the earliest, since they go naturally with the health teaching and the hygiene by which all schooling should begin. Next would come physics. Chemistry would come later still.

It will be impossible, I fear, to allow for more than two years of college for the intending student of medicine with five years of classroom and practical work still ahead of him. We want him to graduate while relatively young, so that he may face the discouragements and trials of early practice and the long uphill climb to a financial competency while still possessed of the resiliency, the buoyancy, the freshness, the enthusiasm, the high courage, and the endurance of youth.

In enumerating these so-called scientific features of premedical education it is important to remember that a slightly greater familiarity with them prior to matriculating in medicine will not compensate for the dwarfing effect of a course restricted to them and unbalanced by studies of a complementary character, bearing always in mind that the object of premedical work is to develop not to indoctrinate. It is many years since M. T. Davison wrote these significant words: "A man who has been trained to think upon one subject, or for one subject only, will never be a good judge in that one; whereas the enlargement of his circle gives him increased knowledge and power in a rapidly increasing ratio."

Mistakes of the Middle Ages.—Education, and as a part of it medical education, in the Middle Ages, was distinctly scientific in character. The strong literary bias and the study of languages which become so marked in the seventeenth and eighteenth centuries did not develop until the Reformation and after. This is not commonly appreciated, but it is a fact. Now, then, when we consider that for 400 years the premedical studies of Europe were grammar, rhetoric and dialectic, making the trivium; and music, arithmetic, astronomy and geometry, making the quadrivium (called collectively the seven liberal arts, but really sciences not arts), and when we realize how absolutely sterile of results was the medical practice to which these premedical studies lead up, have we not some basis in history for questioning the extreme ground which some people take to-day in decrying the value of the humanities and insisting on purely technical preliminaries?

The Place of Latin and Greek.—There is no question that we must give up Greek, and I believe that Homer, Sophocles, and other ancient authors will give more pleasure through the good translation of ripe scholars than from the perspiring schoolboy's own efforts, but I consider that Latin, if ably taught, has a place in our schools. I do not offer in support of this study that it helps in acquiring scientific nomenclature, for that is as roundabout and difficult a way of doing the thing as Charles Lamb's roasting of a pig by burning down the place of his abode. I believe in three or four years of Latin because, along with other and indirect benefits, it is the easiest and surest way of teaching boys and girls to write and speak Englisb correctly. Latin is not an elastic, plastic vehicle of thought like Greek, English, or French but an inflexible one cast in an iron mold. Properly taught to young people of reasonable intelligence the translation of Latin into English prose can be made as fascinating as a picture puzzle. The study of Latin is thus a powerful though indirect method and, because indirect, the easiest way of teaching English grammar. It should be begun early when the necessary memorizing will be least laborious and continued beyond the time when the pupil would be put at English grammar, a study of great difficulty and universally obnoxious. Grammar can be taught, as it were, objectively and solely through Latin, which illustrates the rules of construction in a way that our own language does not.

Need for More Attention to English.—And if I am right in this idea I think the place of Latin is secure in the schools because the one thing that we must insist on is that our boys and girls, whatever their purpose and destiny in life, shall speak and write English correctly. Nowhere in the world is there such need for the teaching of the national language, because nowhere is the school population made up of such a variety of elements, and in the case of many their mother tongue is not English. With no pretension to a mastery of style and no great sympathy with the exaggerated purist, I am nevertheless frequently surprised by the laxness, the inaccuracy, the atrocious barbarisms of the language of daily conversation and even of the public press, the magazines and the books printed in this country. Long observation as examiner on navy boards has brought me to a realization of the sad fact that the young men of America can go through the high school and even obtain a baccalaureate degree, and yet be incapable of writing plain and simple English correctly.

It is to deem knowledge of little value and to take a narrow, selfish and limited view of intellectual pursuits of any kind to deliberately despise and neglect language, the instrument by which we contribute to others and make them sharers of our work and its results. The crying need of premedical scholastic training in America, and of all school and college training at the present time, is for reform in the teaching of English. With all due respect to our capable, earnest, and largely underpaid teachers, I must confess to a feeling that our public school courses are suffering from too large a variety of subjects to permit thoroughness. This is serious, because it is not so much what is taught that counts, as the permanence of the knowledge and the effect on the acquisitive mechanism produced by the way study is conducted. A superficial acquaintance, a smattering, a glossing over a thing is pernicious in the extreme. Better no schooling than such a process. The idea that school must be a place of entertainment and amustment rather than of hard, grinding work, I hold the parents responsible. Too many of them, while contributing little enough toward education in the home, resent the pressure of the teacher and yet desire their children to leave the high school

with a large variety of showy accomplishments.

Finally we have to recognize that in every field of endeavor the best men are largely self-taught. In the progress toward the predestined goal disclosed by the lifting mirage of the future each chooses his own path and has his own peculiar problems to solve. As he advances further and further into the kingdom of truth he discards authority and flings off the fetters of tradition. It is only the mediocre man satisfied with a stereotyped career that can be fully equipped by any system of schooling for all the eventualities of his small and narrow life. What the school and college can do for all is to develop the capacity for true feeling and sound thinking. The medical profession must agitate in season and out of season for a high standard of physical capacity as a basis for intellectual achievement and for normal conduct. It must show its full appreciation of proper values by using every means to divert from its ranks those who have failed to demonstrate the possession of principle as well as of mental proficiency.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held February 17, 1920.

DR. CARY EGGLESTON IN THE CHAIR.

THE program of the evening was furnished by the Staff and Out-Patient Department of Gouverneur Hospital.

Epithelioma of the Jaw.—Dr. LEHMAN presented this case, which he said was quite interesting from the point of view of proving one of the theories supposed to account for malignant growth, namely, that irritation was a factor in the production of malignancy. The patient was a man, 60 years of age, who six years ago began to have pain on the right side of the cheek. A jagged tooth had caused irritation, first what seemed to be an abrasion, then ulceration, and finally epithelioma had developed. After the condition had persisted for 5½ years the man consulted a physician who gave him a mouth wash. Later the tooth causing the irritation was extracted. Finally a piece of tissue was removed for examination and was reported to be epithelioma. The patient had recently been to the Memorial Hospital where the condition was declared to be epithelioma. Two radium treatments had been given, one about three weeks ago and the other the day before. Dr. Janeway expressed the opinion that operation was not necessary and that he could effect a cure within six months by radium treatment, and he also questioned whether the man would stand a radical operation. It was found that the glands in the axilla were enlarged. Dr. Janeway stated that it was one of the peculiar features of epithelioma of the jaw that it did not spread. The ulcerated portion of the epithelioma was on the inside of the cheek; the broken-down area had not spread during the past six months. The first radium treatment was followed by a decided improvement, and further improvement was observed even during the short period that had elapsed since the second treatment.

Dr. L. T. LEWALD said that he thought that because of the glandular involvement in remote parts of the body the possibility of an associated syphilitic lesion should be taken into consideration. It might be worth while instituting antisyphilitic treatment to see what effect it would have on the growth.

Dr. LEHMAN, in replying to Dr. LeWald, said that if the man had syphilis that probably had no effect on the epithelioma. There was no question as to the diagnosis of epithelioma as this diagnosis had been made by two or three different pathologists in different hospitals. He did not understand why the glands were enlarged even though the growth was an epithelioma.

Report of Cases of Methyl Alcohol Poisoning.—Dr. ALEXANDER COMORA read this report. He stated that from Nov. 17, 1919, until Dec. 1, 1919, Gouverneur Hospital received seven definite cases of methyl alcohol poisoning. Subsequently nine cases of suspicious wood alcohol poisoning were reported by their ambulance surgeons, three of whom gave evidence of visual impairment, but all refused to be moved to the hospital and so unfortunately the opportunity was lost of studying the cases and confirming the tentative diagnosis. In view of prohibition the visiting staff had cautioned them to be on the look out for methyl alcohol poisoning and hence every case brought in unconscious was closely observed for symptoms of wood alcohol poisoning. Three of the seven cases died. One patient entered the hospital Nov. 17, 1919, at 8.55 P.M., and passed out at 11.30 P.M. Another patient was admitted Nov. 18, 1919, at 12.10 midnight and died at 12.20; a third patient entered Nov. 19, 1919, at 2.30 A.M., and died at 4 A.M. The history in brief of the patients who recovered was as follows: (1) They had been drinking alcohol; one definitely knew he was taking wood alcohol and had been taking it for several weeks preceding his collapse when he took four ounces at one gulp. (2) Impaired vision. (3) Abdominal symptoms varying from discomfort to severe cramps. (4) Nausea. The physical findings elicited were: (1) Unconsciousness. The recovered patients, however, regained a clear mentality within twenty-four to forty-eight hours. (2) Cyanosis. (3) Pupils equal, enlarged, and in two cases markedly dilated. (4) Pupils showed a sluggish reaction to light. (5) Respirations were deeper and slower than normal, varying between fifteen and twenty per minute. The clinical manifestations in these cases did not show anything definite. The temperature ranged between 98.6° and 100° F. The pulse was increased to between 90 and 120. The urine was normal when made in the routine way. The blood was normal. When the stomach contents were taken early and examined a report of methyl and ethyl alcohol was returned. Dr. Benjamin Schwartz performed the autopsies upon all the cases. Nothing definite or pathognomonic was found. A congestion of all the organs was observed, and a subsequent chemical analysis of the brain, liver, and kidneys showed the presence of methyl and ethyl alcohol in these organs in all three cases. Four patients survived. Two patients recovered their eyesight completely within twenty-four hours; both left the hospital within a week in very good condition. Of the other two, one regained his sight almost entirely; he could differentiate colors and tell time on an ordinary watch, though he still had difficulty in reading. The fourth patient though entirely blind at first left the hospital seeing shadows. Both of these patients though asked to do so had not returned for further study. Our consulting ophthalmologist had made a diagnosis of optic neuritis with beginning optic atrophy in both of these men. The pupils of both were still dilated when they left the hospital but less markedly so than on admission. One of the visiting staff, Dr. Benjamin Schwartz, reported that in some of the cases autopsied at another hospital a chemical analysis of their organs showed the presence of wood alcohol. Clinically these same cases had been diagnosed as cerebral hemorrhage, brain tumor nephritis and surgical abdomen. The writer offered the following conclusions: (1) A definite clinical diagnosis of methyl alcohol poisoning was not always possible. (2) In every unconscious case due consideration should be given to methyl alcohol poisoning. (3) A specimen of urine and of stomach contents should be taken immediately for a chemical analysis for the detection of wood alcohol.

Dr. BENJAMIN SCHWARTZ said the gross pathology of methyl alcohol poisoning showed nothing definitely pathognomonic. The only abnormality present was marked congestion of the internal organs, petechial hemorrhages of the heart and pleura, and fluid blood in heart. Clotted blood was found in one instance. In one of his cases in which the patient was blind no changes were found in the optic nerve and in another case the optic, phrenic, and vagus nerves were examined, and although this subject was blind Dr. Schwartz found no changes in the optic nerves; there were changes, however, in the vagus and phrenic nerves. Changes were found in the retina accounting for the blindness. Birch-Hirshfeld has found changes in the retina consisting of a chromatolysis and destruction of the retinal elements.

Dr. SANDS said that inasmuch as alcohol appeared in the spinal fluid an analysis of the spinal fluid would show its presence if the patient was suffering from

wood alcohol poisoning. The French made use of this method in persons who had committed crimes to determine whether the crime was committed under the influence of alcohol. Alcohol was quite permanent in the spinal fluid and lumbar puncture would reveal its presence.

Dr. C. N. B. CAMAC said that Dr. Schwartz's remarks in reference to the retinal changes were extremely interesting from the point of view of prognosis in relation to the eyesight. Neurologists hitherto seemed disposed to believe that there would be a brief improvement but that ultimately a case of methyl alcohol poisoning went on to optic atrophy. Up to the present time no large number of cases of wood alcohol poisoning had been available for study. It was unusual to see seven cases within such a short period of time. Dr. Camac asked that Dr. Schwartz be invited to tell them more about methyl alcohol poisoning since, as Deputy Medical Examiner, he had had a great deal of experience with this form of poisoning, and everyone connected with a hospital service should be prepared to recognize the condition when he met it. There was no question but that in the cases reported by Dr. Camora, the eyesight had improved, and by following them it might be possible to arrive at a revision of the prognosis in regard to the regaining of eyesight. This report should emphasize the need at the present time of vigilance on the part of physicians in observing every case of unconsciousness as one of possible wood alcohol poisoning.

Dr. SCHWARTZ said that in every case of unconsciousness brought into a hospital the possibility of methyl alcohol poisoning should be considered. The majority of cases in this city went unrecognized or were diagnosed as cerebral hemorrhage, nephritis, or even acute surgical abdomen. One case showed marked abdominal rigidity and a surgeon was called and the advisability of operation discussed. The patient soon went into coma and died. In cases in which wood alcohol poisoning was suspected an examination of the stomach contents should be made. This was done by first oxidizing the stomach contents and then distilling them. To the distillate one-half per cent. resorcin was added and then sulphuric acid; if a red color resulted it indicated the presence of methyl alcohol. In the urine there was a large amount of formic acid and a condition of acidosis was considered to exist clinically. This being so it was possible that the condition might be neutralized by the alkaline treatment.

Report of a Case of Melanoma.—Dr. STEPHEN R. MONTEITH read this report which he said was presented for the following reasons: (1 The volcanic rapidity of its clinical course. (2) The distribution of the metastases as shown at autopsy. (3) The comparatively minute quantity of pigment seen in the tumor masses. The patient was a woman, 23 years of age, admitted to Gouverneur Hospital, Oct. 25, 1919. She was thin and undernourished, though not markedly cachectic. She was markedly dyspneic, somewhat cyanotic, and jaundiced, the jaundice being a lemon tint and not a bright yellow. On the right side of the back, at the lower part of the neck, above the scapula, was a large, firm reddish cauliflower mass, raised above the surface of the skin three-eights of an inch, and measuring 1½ inches transversely by 1 inch vertically. This mass was sloughing and exuded a bloody discharge. Extending outward from this mass was a scar which reached to the shoulder. In the line of this scar and attached to the skin were two firm hard masses. The family and previous history of the patient were negative. The masses above described were first noticed by the patient five years previously, but gave her no concern. She had been in good health until four weeks previous to her admission to the hospital. At that time the hard masses of the right shoulder began to itch, and later ached and pained. Three weeks before admission her physician had incised the most painful of the masses. From this wound, since incision, had grown the cauliflower mass described. The next symptom noted by the patient was a severe, non-productive cough and later pain in the upper right abdomen. This was followed by chills and fever, a cough productive of a thick tenacious sputum, and a few days before admission the patient began to suffer from severe dyspnea. In addition to the masses mentioned above there were other nodules as follows: Over the right side of the back, just within the inner border of the scapula was a mass about ½ by ¼ inches in extent. Over the left side of the back, on a level with the ninth dorsal vertebra was a firm swelling not attached to the skin, but which seemed to be attached to the ribs for about three quarters of an inch. Over the right side of the neck posteriorly, on a level with the sixth cervical vertebra and adjacent to the cauliflower mass, was a nodule one-half an inch long. Below this area and somewhat to the right was another similar nodule, but smaller in extent. Posteriorly, in line with the posterior cervical lymph nodes was a sharp firm mass resembling in consistency a large lymph node. This also was not attached to the skin, as was true of the others. In this area there were other small shotty lymph nodes. The axillary and inguinal lymph nodes were not palpable. No neurological disturbance was noted, a fact emphasized because no post mortem examination of the cranium was made. The heart was normal in size and position, with a harsh systolic murmur heard at the apex and transmitted to the axilla. Examination of the lungs showed that motion was impaired, being greater on the left than on the right side. The right lung on percussion showed flatness below the clavicle. Auscultation over the same areas gave a low-pitched tubular breathing, amphoric in character with no râles present. Posteriorly percussion and auscultation were negative. The left lung anteriorly on percussion or auscultation gave a low-pitched tubular breathing below the clavicle, many loud leathery râles being present. Posteriorly there was complete flatness over the upper half of the lung. Auscultation gave marked tubular breathing. Bronchophony and coarse râles on inspiration and expiration were noted. Thus the left lung clinically was involved to a markedly greater extent than the right lung. Other features of the physical examination, including the reflexes, were negative. The symptoms presented by the patient on admission became progressively more marked. There were frequent stools, those of the first day being brown in color. On the following day they were clay-colored and sticky. A very small amount of urine was passed which was dark amber in color and smoky, the quantity being about 400 c.c. in 24 hours. Tests for albumin and glucose were negative. A few granular casts, blood cells, and erythrocytes were found. The blood examination showed erythrocytes 4,750,000; leucocytes 23,500; polymorphonuclears 85 per cent.; small mononuclears 12 per cent.; large mononuclears 3 per cent.; hemoglobin 70 per cent. Suspecting a melanotic tumor, the test for melanin was applied to the urine and found to be positive. This excretion was one of the many interesting features of melanotic tumors and was brought about as follows: By the metabolic processes of its chromatophore cells the tumor produced melanin in excess. This pigment entered the blood and was excreted by the kidney glomeruli as pigment granules. Or, as others held, the melanin in the blood as changed by the liver to colorless melanogen, which was in turn excreted by the kidney. The essayist described the test for determining the presence of true melanogen. Within a few hours after admission the patient's respirations had increased to 60 per minute, and the pulse rate to 160. She became progressively weaker and finally died Oct. 27, having been in the hospital forty hours. Autopsy was performed by Dr. Benjamin Schwartz of the Gouverneur staff. It centered largely around the distribution of the metastatic processes, and was given quite in detail. The pleural sacs were apparently practically obliterated by adhesions. The pericardial sac was distended and contained an ounce of clear yellow fluid. The first metastases were found in the left ventricle there being four firm masses projecting from the surface, grawish-white in color, homogeneous, firm, and well circumscribed. The anterior mediastinal lymph nodes were involved. The right lung was lumpy in consistency and contained numerous large well circumscribed oval tumor masses. In the center of the tumor mass of the left lung were two blackish circumscribed nodules about three-eighths of an inch in extent, these being the only ones of the enormous number of tumor masses which showed any black pigmentation whatsoever, macroscopically. Further invstigation revealed a tumor mass in the vault of the diaphragm

and tumor masses throughout the pancreas. The liver, gallbladder, and spleen, two organs commonly the seat of secondary tumor growth, were uninvolved. The adrenals, kidneys, bladder, ovaries, stomach, and mesentery were involved. The uterus was much enlarged and contained a six months fetus; the test for melanin applied to the amniotic fluid was negative permission to open the cranium could not be secured, thus valuable information as to the possible seat of the original tumor or of extensions to the central nervous system could not be obtained. In drawing a practical lesson from this case, the essayist stated that they had here a young woman admitted to the hospital with a diagnosis of pneumonia, a disease with a very striking picture, rapid breathing, cyanosis and dyspnea, and profuse signs in the chest, hardly a picture of a chronic tumor growth. Such a picture could not have been produced by a slow gradual metastatic growth. The reasonable conjecture was that the disturbance of the afore-mentioned tumor caused a volcanic disturbance of the chromophores, which, as was well known, was possible, and that the subsequent findings on the autopsy table were the direct result of the incision to which the patient was subjected. The chief interest lay in the extreme rapidity with which the colossal changes were produced. It must be concluded that the striking findings were produced in the space of about four weeks. It was of course a hackneyed suggestion that melanomas must not be interfered with except when the surgeon was prepared to do a very radical operation.

Dr. SCHWARTZ said one very rarely had the opportunity of performing an autopsy on a case of melanotic sarcoma. In some 4000 autopsies this was the first melanotic sarcoma he had encountered. Dr. Symmers in some 1300 autopsies had met three cases and in these there were also metastases in the heart. In Dr. Monteith's case microscopical examination of the skin showed no pigmented cells; the only pigmentation found was in the tumor of the left lung.

Dr. CAMAC referred to the fact that one of the original foci in the eye in these cases of melanoma had at times been diagnosed by the oculists as glaucoma. Dr. Hart recently reported a case in which the oculist made a diagnosis of glaucoma. In another case specimen and photograph of which were here shown a similar diagnosis was made at an eye hospital and the eye removed and placed in a bottle. The patient from whom the eye had been removed later developed a large growth of the liver. The physician who saw her went back to the hospital and procured the eye. A section of this eye was examined and showed melanotic sarcoma, so that it was evident the liver growth had had its origin many months before the liver involvement from the eye but that the condition had been overlooked in the erroneous diagnosis of glaucoma made. In the case Dr. Monteith reported it was difficult to say where the origin was. It was not a skin growth but seemed to be beneath the skin in the muscles. The important point for the clinician to remember was that in cases of growths of this kind if there was involvement of the eye the oculist might diagnose the condition as glaucoma, and if the condition was not glaucoma but melanotic sarcoma it would surely lead to death in a short time. Another point was the ease with which melanotic sarcoma could be diagnosed. The urine if allowed to stand and become oxidized or if oxidized by a chemical reagent presented the dark brown or black color of the specimens here presented. Still another point to be emphasized was that care should be exercised in incising these skin growths, as a volcanic metastasis might quickly follow.

Brain Lesions in Gas Poisoning.—Dr. BENJAMIN SCHWARTZ spoke briefly on this subject. He stated that the gross lesions of the brain in gas poisoning were symmetrical softening of the anterior, inferior, and internal portions of the lenticular nucleus, together with a red color in these areas. These changes did not occur unless the individual had been unconscious from carbon monoxide poisoning for 48 hours or more. Oftentimes these infarcts were converted into cystic cavities. These infarcted areas were due to thrombosis of the arterial vessels. Kalisco was the first to point out that the artery producing these lesions was a small thread-like artery given off from the anteriorcerebral artery which had a peculiar course and turned on itself backward at an angle of 180 degrees. He believed that in gas poisoning the blood pressure was lowered and produced stasis which led to a diapedesis of the red blood cells and thrombosis. In all cases the lenticular nucleus was affected, and in every case in which this condition was found in the lenticular nucleus the patient had been unconscious for 48 hours. Recently he had seen a case with unusual lesions in the brain. This girl was taken from a room in which two other persons were found dead, the decomposition indicating death took place at least two days ago. The gas was turned on though no longer escaping as the meter supplying the gas was a twenty-five cent deposit meter and the supply had been exhausted. This girl was admitted to Gouverneur Hospital in an unconscious condition, a temperature of 102° to 104° F., and a normal blood count. She lived 43 hours after admission. From the temperature and the few physical signs present it was thought she had a bronchial pneumonia, and these were the lesions usually present in cases of gas poisoning. This patient went into coma and died. At autopsy, bronchopneumonia was found, but in addition the peculiar thing found was not a softening of the lenticular nucleus but of the optic thalamus, which was red in color. Examination of the infarcted areas showed the veins thrombosed and no thrombosis in the arteries. This condition was due not to gas poisoning but to infection and thrombosis of the veins. The usual finding in cases of poisoning from carbon monoxide gas was the softening of the anterior, inferior and internal portions of the lenticular nucleus.

Dr. CAMAC recalled that this was the popular method of suicide at the time of the French Revolution, and was said to be a very delightful way of passing out. The method was popular among the unhappy victims on account of its euthanasic qualities in preference to the guillotine. Carbon monoxide gas had not been used in warfare because it was not heavier than air and would not cling to the ground. This was illustrated by the following incident. Upon opening the door of a room from which came a strong odor of gas, a small dog leaped up and barked. On a low seat was a child slightly overcome by carbon monoxide gas, and in a chair was a woman who had been killed by the gas. The child recovered. This was a very interesting demonstration of the effect of gas from above downward, the gas having killed the woman and stupidfied the child while it did not harm the dog. The small red pinpoint lesions in the lenticular nucleus could be seen in the gross and often constituted the only evidence of gas poisoning.

Dr. SCWARTZ, in closing, again emphasized the fact that the changes occurred on the anterior, inferior and internal portions of the lenticular nucleus and in the case cited by Dr. Globus he thought the ganglionic changes accounted for the symptoms. So far as the bleeding was concerned they found stasis of the arteries and diapedesis into the lenticular nucleus. If there had been a general destruction of blood vessel tissue in the case cited it was rather strange that the evidence should be found only in this part of the blood supply.

Pulmonary Syphilis.—In a paper from the Department of Medicine of the Jefferson Medical College, Elmer H. Funk expressed his belief that late syphilis of the lung occurs clinically more often than is generally taught. Diagnosis is difficult and judgment may have to be suspended until lues has been controlled by treatment, when "apical râles" will clear with the associated bronchitis if signs are due to syphilis. The author reports in detail three cases of what he believes were pulmonary syphilis that have come under his own observation. In arriving at a diagnosis the following points are important: (1) the history; (2) signs of syphilis in other organs; (3) the location of the lesion —syphilis usually involves the hilum areas of the bases, unusually rare locations for primary tuberculosis lesions; (4) the persistent absence of tubercle bacilli when signs of advanced pulmonary disease are evident; (5) a positive Wassermann reaction when all tests for tuberculosis are negative; (6) certain roentgenographic features which the author gives in detail; and (7) the response to antisyphilitic treatment.—*Amer. Rev. of Tuberculosis.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

CALIFORNIA STATE BOARD OF EXAMINERS.

October, 1919.

(*Concluded from page* 675)

SURGERY.

(Answer ten questions only.)

8. What conditions require tracheotomy, name the diseases in which they occur. Describe the operation.
9. Discuss briefly sacroiliac relaxation.
10. Give the indications for paracentesis tympani. Describe the operation.
11. Give the symptoms of nephroptosis. Discuss briefly the treatment, with special reference as to relative value of operative and nonoperative measures.
12. Give the different causes of traumatic keratitis, with the treatment.

OBSTETRICS AND GYNECOLOGY.

(Answer ten questions only.)

1. Give differential diagnosis between right-sided salpingitis, tubal pregnancy, and appendicitis.
2. Define menorrhagia, metrorrhagia, dysmenorrhea, amenorrhea, dystocia.
3. Give the origin and distribution of: (*a*) The blood supply of uterus and ovaries; (*b*) nerve supply of uterus and ovaries.
4. Differentiate a four months' pregnancy from four other conditions causing enlargement of the abdomen.
5. (*a*) Name the indications for version. (*b*) Describe the operation of podalic version.
6. Describe the operation for vaginal hysterectomy.
7. Name the female genital organs: (*a*) Internal, (*b*) external.
8. Post-partum hemorrhage: (*a*) Give four predisposing causes; (*b*) give four immediate causes; (*c*) give treatment.
9. Describe mechanism of labor in R. O. A. position.
10. Discuss vomiting of pregnancy.
11. Discuss artificial infant feeding during the first three months.
12. Describe the change in the fetal circulation upon ligation of the umbilical cord.

ANSWERS.

SURGERY.

8. *Indications for tracheotomy.*—(*a*) Certain cases of laryngeal obstruction caused by diphtheria; (*b*) some forms of chronic ulceration of the larynx, where respiration is dangerously interfered with, such as syphilitic and epitheliomatous ulcerations; (*c*) cases of severe stenosis of the larynx dependent upon cicatrization, or when the interior is filled up with proliferating growths, such as papillomata; (*d*) for the removal of foreign bodies from the trachea, or bronchi, in cases where upper bronchoscopy has failed; (*e*) as a preliminary to the performance of some severe operation about the lower part of the pharynx and larynx. —(From Waring's *Operative Surgery.*)

Tracheotomy.—"The patient is placed on the back with a narrow pillow under the neck. Chloroform or cocaine can be used as anesthetics. An incision, one and a half inches long, is made downward from the cricoid cartilage, keeping strictly in the mid-line. The incision is deepened till the tracheal rings and isthmus are exposed. Enlarged veins give trouble during this stage if there is dyspnea. A director-hood is thrust into the trachea, and the point of a knife is slid along the groove to open the trachea from below upward. The patient is allowed to cough for a few minutes while the wound is kept open with dilating forceps; then the tube is tied in."—(*Aids to Surgery.*)

9. *Sacro-iliac relaxation.*—"When some of the sacro-iliac ligaments are ruptured or relaxed we get the chronic condition called sacro-iliac relaxation. When this exists the individual may injure the articulation again and again because of its unsteadiness, he may now and then have trouble, he may be in a constant condition of helplessness, with backache, groinache, pain in the hip and over the ischial tuberosity, lumbar rigidity producing lateral curvature, etc. *Treatment:* After securing by manipulation normal relations in the articulation, insist on rest and apply a spica bandage of plaster of Paris or a brace. If there is marked tendency to displacement, ankylosis may be secured by operation. Fixation by a bone-graft from the tibia should give the most rapid and permanent result."—(Da Costa's *Modern Surgery.*)

10. *Indications for paracentesis of the membrana tympani.*—To evacuate pus in the tympanum (and so to relieve pain, limit the infection, shorten the disease, and prevent complications); for enlarging perforations which are too small to allow adequate drainage; it is employed also in certain catarrhal and inflammatory conditions of the ear.

The parts are to be sterilized, an anesthetic (local or general) given; and the incision is then made with a slender, sharp-pointed knife. A speculum and adequate illumination will be necessary. The particular quadrant which should be incised depends upon the condition calling for the operation. The incision should be made sufficiently long; a mere puncture is not sufficient. If possible the incision should be so placed that the opening will extend from near the floor of the canal upward and through the bulging portion of the membrane. The surgeon should avoid touching the auditory ossicles.

11. *Symptoms of nephroptosis.*—"A movable kidney is often discovered by accident, and may be entirely free from symptoms. In some cases the patient comes under observation because she has observed a movable lump in the abdomen, which on handling is painful, the pain being often associated with nausea and vomiting. In other cases pain and vomiting bring the patient under observation, the doctor discovering the movable kidney. The pain is referred to the back, or perhaps shoots along the ureter to the groin, testis, or labium majus. Vomiting is a significant sign, and the surgeon should never omit to examine the loins in cases of obstinate vomiting with no apparent cause. Periodical exacerbations of these symptoms, with a temporary diminution in the amount of urine, result from kinking of the ureter (*Dietl's crises*); sudden relief, followed by an increased flow of urine, possibly containing some muco-pus, indicates that the organ has returned to its normal situation. Repeated attacks of this type may result in pyelitis and hydronephrosis. On examining the abdomen, a movable tumor can often be observed with ease if the abdominal parietes are not loaded with fat, and on manipulation pain and vomiting may be induced. The adoption of the genu-pectoral position will sometimes enable a movable kidney to be more certainly felt, while a distinct loss of resistance is noticed external to the erector spinæ on the affected side. The patient is usually of a neurotic type, but possibly this may result in part from the mobility of the organ which necessarily involves a certain amount of traction upon the sympathetic centers in the abdomen. Evidence of the displacement of other abdominal viscera is often found, so that the detection of a movable kidney does not necessarily explain the whole case, or indicate operation. After many an operation for movable kidney, the symptoms (pain, vomiting, etc.) have persisted, even though the organ remained anchored to the abdominal wall.

Treatment.—In the great majority of cases of movable kidney operation is not required, and indeed it is usually unwise to tell the patient that such a condition is present. If it is associated with marked ability, bodily or nervous, and perhaps with general enteroptosis, a rest-cure in bed for six weeks, with abdominal and general massage and an abundance of milk and fatty foods, will do much to steady the kidney and improve the general condition. The application of a carefully fitted kidney support will then suffice to keep her comfortable. This may consist of an abdominal truss, with an end shaped like a cup to fit over the kidney, or of an air-cushion fitted into an abdominal belt. The cushion should be triangular in shape, its sides corresponding to the costal border, Poupart's ligament, and the linea semilunaris; it is put on in the recumbent posture, and for choice with the pelvis raised. The

indications for operation are: (1) Extreme mobility, so that the organ cannot be fixed by a support; (2) extreme tenderness, so that a support cannot be tolerated, and even ordinary handling causes discomfort and perhaps vomiting; (3) the recurrence of acute attacks of pain and vomiting (*Dietl's crises*); (4) persistent discomfort in the loin, combined with dyspeptic symptoms, vomiting and a great variety of neurasthenic manifestations: as a rule a kidney sufficiently mobile to produce such symptoms is tender to the touch, and examination causes pain and nausea; and (5) the supervention of hydronephrosis or pyelitis."—(Rose and Carless' *Surgery.*)

12. *Traumatic keratitis* may be caused by foreign bodies, such as particles of sand, cinders, splinters of iron, particles of emery, or particles of oyster-shell; also by erosions, wounds, burns and scalds. Foreign bodies should be removed with the aid of cocaine or holocaine, this is to be followed by the use of atropine to allay the inflammation, and bandaging. Erosions are treated by the instillation of an antiseptic lotion, and the use of atropine and holocaine and bandaging. Burns and scalds demand the prompt removal of the foreign matter, irrigation, the instillation of oil or atropine, and rest to the eye.

OBSTETRICS AND GYNECOLOGY.

1.

APPENDICITIS.	SALPINGITIS.
1. No previous local disturbance.	1. Genitourinary functions previously disturbed. Usually a history of gonorrheal or puerperal infection.
2. Chill usually absent.	2. Chill may precede fever.
3. Pain in right iliac region, sudden onset, acute, and not radiating to thighs.	3. Gradual onset, pain dull, continuous, and radiating.
4. Fever of variable degree.	4. Fever often entirely absent.
5. Muscular rigidity on right side of the abdomen.	5. No muscular rigidity unless complicated by peritonitis.
6. Inflammatory exudate about appendix three to five days after onset of symptoms.	6. Inflammatory exudate in the pelvis felt by vaginal examination at the onset of the symptoms.
7. Vaginal examination is rarely painful in appendicitis.	7. Always painful in tuboovarian disease.

—(Findley.)

Differential diagnosis between ectopic pregnancy and acute appendicitis.—Appendicitis in its onset and in its further course may very closely simulate a ruptured tubal pregnancy, but in appendicitis there are none of the general and local signs of pregnancy. There is often a history of previous attacks, with intervals of complete or partial freedom from pain and intestinal disorder. The distress is almost always confined to the right side, while in ectopic pregnancy it is often referred to the median line or left side. In both of these conditions the pain appears suddenly, and may be intense; in ectopic pregnancy it may be momentary, while in appendicitis it usually persists throughout the attack. The sudden pallor and collapse frequently following immediately upon the rupture of a tubal pregnancy never occur in appendicitis. It is at this time that a most suggestive sign appears, *i. e.*, uterine hemorrhage accompanied by a discharge of decidual membrane. In such an event there can be no further consideration of appendicitis. Much dependence is placed upon the further finding of an enlarged soft uterus and an irregular mass attached to it at the side or lying behind the uterus. When doubt exists, the uterus may be explored with a curette and the scrapings examined for decidual tissue."—(Findley's *Diseases of Women.*)

2. *Menorrhagia* is a condition characterized by excessive loss of blood at the menstrual periods.

Metrorrhagia is a hemorrhage from the uterus at other than the menstrual periods.

Dysmenorrhea is unduly painful menstruation.

Amenorrhea is absence of menstruation during the period of sexual activity.

Dystocia is labor in which there is any departure from the normal.

3. "The *blood* supply of the *uterus* is derived from the uterine artery, a branch of the internal iliac, and the ovarian, from the abdominal aorta. The uterine artery reaches the uterus at a point opposite the supravaginal portion of the cervix and crosses in front of the ureter at a distance of ¾ inch from the cervix. It then bends upward and runs close beside the body of the uterus, between the folds of the broad ligament, giving off a number of branches which supply the uterine wall, and at the angle of the uterus anastomoses with the ovarian artery. The spiral course of the uterine artery is for the evident purpose of allowing for the increased size of the uterus during pregnancy without causing tension of the vessels. The *veins of the uterus* take their origin in the venules of the mucosa and muscularis. The branches which traverse the muscularis are by far the most important. In the pregnant uterus they undergo enormous development and form the uterine sinuses. The uterine veins terminate in the venous plexuses of the broad ligament and anastomose with those surrounding the base of the bladder, the vagina, and rectum. The *ovary* is supplied by the ovarian branches of the abdominal aorta, which enter the pelvis in a fold of the broad ligament, and thence continue to the attached border or hilum of the ovary. They anastomose with the uterine arteries. The *veins* form a plexus near the ovary and empty into the ovarian vein, which in turn empties into the renal vein on the left side and into the inferior vena cava on the right. The *nerves of the uterus* are derived from the third and fourth sacral, and sympathetic branches from the hypogastric and the renal plexuses. The *cervix* is poorly supplied with nerves. The *nerves of the ovaries* are derived from the ovarian plexus, a continuation of the renal plexus.—(From Campbell's *Surgical Anatomy.*)

4. *Pregnancy at four months.*—The tumor is hard and does not fluctuate, and is situated in the median line; the cervix is soft, and some of the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid.—Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

Ovarian cyst.—Absence of the chief signs of pregnancy; there may be the characteristic facies, the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

Ascites.—Absence of the signs of pregnancy; the abdomen is distended, but the shape varies with the position of the patient; on lying down there is bulging at the sides, the tumor fluctuates, and percussion shows dullness in the flanks, with resonance in the median line, but the dullness varies with the position of the patient.

Subinvolution of uterus.—The uterus does not increase in size, there is a leucorrhea, there is generally pain in the back or ovarian region, there is a history of irregular (and profuse) menstruation, and the signs of pregnancy are absent.

5. *The indications for version* are: (1) In transverse presentations; (2) in placenta prævia;* (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother, and (7) in any case where speedy delivery is imperative.

Braxton Hicks' method of bipolar (podalic) version.—"The patient should be placed in the lithotomy position and be deeply anesthetized, to relax the parts and allow the whole hand to be pushed into the vagina. The external hand is placed over the breech, so as to depress it; while the presenting part is tilted away from the brim by the fingers inserted through the os. The fingers press against the front of the child and

flexion is lessened. When the head is out of the brim the external hand can be used to elevate it towards the fundus. As soon as a knee or foot comes within reach of the internal fingers, it should be caught and brought into the brim, the membrane being ruptured at the same time. If the os is fully dilated, delivery may be finished at once, as in an ordinary breech case; but if the os is only partially dilated, it must be left to nature, to allow the dilatation."—(Jardine's *Delayed and Complicated Labor.*)

6. *Vaginal hysterectomy.*—"The patient is prepared as for any pelvic operation, and anesthetized. The cervix is sterilized with the cautery, and pulled down by a double tenaculum. The cervix is freed from its vaginal attachments by a circular incision. The bladder is pushed up anteriorly, with gauze, a retractor placed under it for protection, and the anterior pouch of the peritoneum caught and opened. The uterus is caught with a volsellum and anteverted through this peritoneal opening. The broad ligaments are caught in clamps, and cut through near the uterus. Three clamps to each side are needed. A better, though more difficult plan, is to ligate the broad ligaments with three ligatures, cutting free each section as it is tied, and holding the stumps with a hemostat. When the broad ligaments are tied or clamped and cut, the peritoneum is opened posteriorly, and the uterus removed. If ligatures have been used, the stumps of the broad ligaments are sewed together, the peritoneum and vaginal walls closed over them with number 3 chromic catgut. If clamps were used, the pelvis and vagina around the clamps is packed with gauze, and the handles of the clamps so supported by a suspensory bandage that the blades are not dragged upon. Clamps are cautiously removed, after seventy-two hours."—(J. C. Hirst's *Manual of Gynecology.*)

7. The *internal genital organs of the female,* are: The uterus, Fallopian tubes, and the ovaries. The *external organs* include: The mons Veneris, vulva, labia majora, labia minora, clitoris, vestibule, Bartholin's glands, hymen, and vagina.

8. POST-PARTUM HEMORRHAGE. *Four predisposing causes.*—(1) Multiparity; (2) hemorrhagic diathesis; (3) precipitate labor; and (4) overdistension of the uterus.

Four immediate causes.—(1) Mismanagement of labor, such as emptying the uterus too rapidly; (2) placenta prævia; (3) retained placenta or clots; and (4) an overdistended bladder.

Treatment.—Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other on the outside make firm pressure. A hypodermic of ergotin or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging of gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

9. *Mechanism of Labor in R. O. A.*—"(1) Accommodation of the size of the fetal skull to the size of the pelvic canal by flexion; accommodation of the shape of the fetal skull to the shape of the pelvic inlet by moulding; accommodation of the direction of the head to the direction of the pelvic canal by lateral inclination. These movements occur prior to labor, when the head enters the pelvic inlet with the subsidence of the uterus. (2) Further flexion, moulding, and accommodation of the head to the pelvis by lateral inclination, when labor pains appear, and the head is subjected to a propulsive force and to the resistance of the lower uterine segment, the cervix, and the pelvic walls. (3) Dilatation of the lower uterine cavity and of the cervical canal. (4) Descent of the head to the pelvic floor, mainly by an extension of the fetal spine. The fetal body, as a whole, is not yet propelled along the birth canal, because, during a pain and while the head is obviously descending to the pelvic floor, the fundus uteri and the breech do not sink to a lower level. On the contrary, there is a slight elevation of the fundus, and elongation of the uterus, and the distance between the head and the breech increases during a uterine contraction. (5) Anterior rotation of the occiput. (6) Propulsion and extension of the head in the direction of least resistance under the pubic arch until it is delivered, again following the direction of the lower pelvic floor, which is now upward, forward, and outward. (7) Restitution. The rotary movement of the head is not followed by the shoulders. As the former escapes from the vulva with the sagittal suture running anteroposteriorly, the neck is necessarily twisted. As soon as the head is released from the forces which compel its rotation, it immediately resumes its natural relationship with the shoulders, which lie with their long axis in the oblique diameter of the pelvis. (8) External rotation. This movement of the head is explained by the movement of the shoulders within the birth canal. (9) Descent, rotation, and birth of shoulders. The anterior, or left shoulder first strikes the resistance of the pelvic floor. In obedience to the universal law that whatever portion of the fetal body first encounters this resistance is directed downward, forward, and inward, the anterior shoulder is compelled to travel in these directions by a rotary movement of the shoulders on the spine. The anterior shoulder finally appears under the arch of the symphysis; unable to move further forward, the posterior shoulder and arm are propelled over the floor of the pelvis and are born, their escape being followed by the birth of the anterior shoulder and arm. (10) Delivery of remainder of the body by a movement so rapid that the eye cannot well follow it, the birth canal being so widely dilated that its walls offer no resistance to the escape of the small and compressible thorax, abdomen, and lower extremities."—(From Hirst's *Obstetrics.*)

10. The ordinary morning sickness is a mere symptom, has no significance, and seldom gives any trouble or needs treatment. The pernicious vomiting is very severe, is probably due to reflex nervous disturbances. It may endanger the life of mother anad child, and may necessitate the interruption of the pregnancy. If the cause can be found it should be removed, and every possible care must be taken of the woman. Other *causes of vomiting in pregnancy* are: (1) Reflex disturbance, due to rapid growth and excessive distention of the uterus; (2) disease or displacement of uterus, tubes and ovaries; (3) disease of pelvis or gastrointestinal tract; (4) excessive sexual intercourse; (5) renal disease or disturbance.

Pernicious vomiting in pregnancy may arise from a variety of causes. The most common are: Reflex disturbance, caused by the rapid growth and distension of the uterus; some pathological condition of the uterus or its adnexa; some pathological condition of the gastrointestinal tract; excessive sexual intercourse; kidney insufficiency, or some other form of faulty nitrogenous metabolism. The principal symptom is continuous vomiting, which results in exhaustion and death unless relieved. The urinary examination shows diminution of urine and total nitrogen; ammonia is in excess, indoxyl and skatoxyl are increased. Leucin, tyrosin, albumin and sugar may be found. The *treatment* consists in rest in bed in a quiet, darkened room and the administration of easily digested foods, such as milk, broths, eggs, etc. A careful search must be made for some local exciting cause, and if such condition is found it should receive appropriate treatment. Sexual intercourse should be interdicted. The bowels should be kept freely open. Sodium bromide, camphor, cocaine, silver nitrate, cerium ovalate, hyoscine hydrobromide, antipyrine, etc., are among the drugs used internally. Rectal alimentation may be necessary, and, as a last resort, dilatation of the cervix and internal os, or abortion may be performed.

11. *Artificial feeding is indicated.*—If the mother dies; absence of breast milk, eclampsia, tuberculosis, septic infection, severe hemorrhage, or chorea on the part of the mother; and in case of persistent loss of weight of the child.

Proper modification of cow's milk includes dilution, and the addition of cream and sugar of milk.

For a newborn infant, take the top 9 ounces from a quart of good milk, of this use 2½ ounces; to this 2½ ounces add one ounce of milk sugar and 17½ ounces of boiled water. This will give 20 ounces. The infant should receive about half an ounce every two hours

for the first day, and about one ounce every two hours for the next six days. During the night the infant should be fed twice. This mixture is only suitable for the first week.

The following table is compiled from several in Kerley's book on *Treatment of Diseases of Children:*

	3d to 10th Day.	10th to 21st Day.	3d to 6th Week.	6th week to 3d Month.
Gravity cream	½ oz.	1½ oz.	3½ oz.	4 oz.
Milk	3 oz.	5 oz.	8 oz.	12 oz.
Milk-sugar	1 oz.	1½ oz.	3 oz.	4 oz.
Lime-water	½ oz.	½ oz.	2 oz.	3½ oz.
Boiled water to make	16 oz.	24 oz.	32 oz.	52 oz.
Feedings in 24 hours	10	9 to 10	8 to 8	7 to 8
Amount at each feeding	1 to 1½ oz.	1½ to 2 oz.	3 to 3 oz.	3½ to 4 oz.

12. *Changes that occur in the fetal circulation at birth.*—The hypogastric arteries dwindle and close, the foramen ovale becomes obliterated, the ductus arteriosus and ductus venosus become obliterated, the umbilical vein becomes impervious, and the Eustachian valve atrophies.

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular state.

Acute Epidemic Encephalitis.—This term is preferred by Sicard because apparently not all cases show lethargy, while some have been expressed as myoclonus. He has recently seen three cases of which two were myoclonic and one lethargic. Exhibition of convalescent serum in the spinal canal appeared to cure one of the myoclonic cases.—*Le Bulletin Médical.*

Therapeutic Hints.

Ringworm of the Nails. — In general practice, according to Robert Craik, onychomycosis is comparatively rare, and its treatment is apt to be superlatively disappointing. In two cases (both in women) he found the following treatment successful: A lotion of ℥j of salicylic acid in ℥jss of methylated spirit, to be painted on after scraping every night, and without scraping every morning, and to be used for three months or longer.—*British Medical Journal.*

Mercuric Iodide in Syphilis.—R. L. Spittel reports a method of administering mercury and iodide in the treatment of syphilis which he has found superior to any other. At the beginning of the war, when there was a likelihood of a shortage of salvarsan, he experimented with arsenic, mercury and iodide, taking as his working hypothesis dosage to the point of tolerance by the intravenous route. An experience of over 4,000 of these injections, during a period of four years, convinced him of the value of the solution used. It is a valuable adjunct to the treatment of syphilis with salvarsan; the combination establishing a cure (as gauged by Wasserman tests, provocative and otherwise, at varying intervals) more quickly and permanently than by any other method. The solution has the following composition:

Mercuric iodide ..... 50 gr. (3.24 g.)
Sodium (or potassium) iodide ... 8 dr. (28.42 g.)
Phenolphthalein (0.5% solution)...20 m. (1 c.c.)
Sodium hydrate (25% solution)..... about 2 dr.
Distilled water.....to 40 oz. (1000 c.c.)

The dose for an adult is 8 to 12 c.cm. given intravenously with a 20 c.cm. or a 30 c.cm. syringe. The required dose is filtered off through aseptic cotton wool and drawn into the syringe, which is then filled to its full capacity with strained sterile or distilled water. The number of injections and the interval between them vary with the individual case. An ordinary case of secondary syphilis may be treated with five or six injections each of salvarsan and mercuric iodide, given at intervals of from seven to ten days alternately, either in varying sequence or sometimes in successive courses.

In addition to this it is well to safeguard the patient by prescribing mercurial treatment by mouth or inunction (measures which have the advantage that the patient carries them out at home) for periods varying from eight to twelve months, according to the demands of the case. Mercury, in the form of grey powder, is to be taken for six weeks; this is to be followed by an interval of one month, in the middle ten days of which an iodide mixture is given, *e. g.*:

℞ Potassii iodidi ..... 5 to 20 gr.
Liq. arsenicalis ..... 4 m.
Extracti sarsæ liq..... 1 dr.
Syrup. glycerophosph. co..... 1 dr.
Infus. cinchon ..... ad ½ oz.

Sig. To be taken in a glass of milk or water twice a day.

These oral courses of mercury and iodide are to be continued for at least a year, or more if necessary.—*The Lancet.*

AN ACCOUNT OF POISONOUS SUMACHS, RHUS POISONING, AND REMEDIES THEREFOR.

BY W. L. MCATEE,

WASHINGTON, D. C.

ASSISTANT BIOLOGIST, U. S. BIOLOGICAL SURVEY.

THE plant family to which the poisonous sumachs belong, namely the Anacardiaceæ, is characterized by numerous species having acrid, caustic, or poisonous juices. Among the more or less well-known kinds that possess an irritant poison are the Cashew-nuts (*Anacardium* spp.), the marking-nuts (*Semecarpus* spp.), and some species of pepper-trees (*Schinus*) and pistacio (*Pistacia*), in addition to the poisonous sumachs themselves, members of the genus *Rhus*, in a broad sense. At least 11 exotic species of *Rhus* have been recorded as poisonous, the most noteworthy of which is *Rhus vernicifera* from which Japanese lacquer is obtained.

American Poison Sumachs.—The American poisonous species include the coral sumach (*Rhus metopium*), the poison sumach (*R. vernix*), the poison oak (*R. diversiloba*), and the poison ivies (*R. toxicodendron*), a group variously considered to include from one to eight or more species.

The coral sumach occurs only in southern Florida, and is known also by the names, poisonwood, hog gum, and doctor gum.

Poison sumach is found throughout the states east of the Mississippi Valley. For this plant which forces itself on the public attention, I have found the following vernacular names: poison ash, poison elder, poison dogwood, poison oak, poison sumach, poison swamp sumach, poison-tree, poison-wood, poison-wood tree, swamp sumach, white sumach, dogwood, swamp dogwood, varnish-tree, quick-will, thunderwood, sulphur-wood, mercury, and in use among the French-Canadians *l'arbre à puce.*

The poison oak (*Rhus diversiloba*) is confined to the Pacific Coast; a book name is California poison sumach, and the plant is further known in English as poison ivy, California poison vine, and in Spanish as *yeara*, and *hiedra* (or *yedra*).

The poison ivies of the variable and possible polyspecific group are distributed from British Columbia and Nova Scotia south to Arizona and Florida. Excluding book names applied to the various segregates, the following vernacular nomenclature has been found for these plants: Poison ash, poison creeper, poison ivy, poison mercury, poison oak, American poison vine, climbing ivy, three-leaved ivy, wild-ivy, climbing sumach, trailing sumach, climath, shoe-string weed, mercury vine, black mercury, black-mercury vine, and various modifications of the word mercury, as markery (markory, markry), markweed, and even pickry (picry).

This is not the place for a botanical description of these plants, such as can be gleaned from the various manuals, but two points relating to the size attained may be mentioned. Poison sumach often becomes a small tree and has been known to attain a height of 25 feet and a diameter of 10 inches; while poison ivy may reach a diameter of several inches and may climb to the tops of some of the taller trees.

The Poisonous Principle of the Toxic Sumachs.—Whatever form a particular species of *Rhus* may assume, whether creeping or climbing vine, shrub or tree; whatever species even it may be, the poisonous principle seems to be the same. This conclusion is the result of modern studies, the latest investigations in a long series, which have been remarkable for the diversity of their results, and which it will be interesting to review.

In 1797 van Mons[1] announced that the poisonous principle of *Rhus radicans* was a gaseous hydrocarbon which emanates from the plant only at night or on cloudy days. In 1825 Lavini[2] agreed that the poison was a gas, but that the hydrocarbon given off by the plant was not poisonous. Thirty-three years later, in 1858, Khittel[3] pronounced the poison to be a volatile alkaloid, and in 1865 Maisch[4] controverts this by attributing the poisonous properties to a supposed new volatile acid, he calls toxicodendric acid. This was later proved to be acetic acid. In the same year Buchheim[5] asserted that the poisonous element is cardol.

In 1882, Burrill[6] in conformity to a whilom fad of tracing every trouble to germs or bacteria, launched the theory that *Rhus* poisoning is due to an organism he called *Micrococcus toxicatus.* This theory received little support and was abandoned later by its proposer. In 1893, Mathews,[7] evidently impressed by the acid theory, called the poisonous principle of varnish trees in China, tsihic acid, from the Chinese name of the varnish, tsih. Four years later in 1897, Pfaff,[8] as a result of the most scientific investigation of the subject up to that time, proved that the volatile toxicodendric acid of Maisch is acetic acid, and states that the poisonous principle is a nonvolatile oil which he calls toxicodendrol. However, the best of findings relating to *Rhus* poison, seem liable to overturning, as 9 years later, in 1906, we find Acree and Syme[9] attributing the irritant effects of *Rhus* to a complex substance of a glucosidal nature, which apparently is to some degree volatile. In publications dated 1905 to 1907 Stevens and Warren[10] asssert that the poison is

resinous and nonvolatile, and in 1907, also, Majima and Cho,[11] Japanese chemists, call it urushinic acid. A year later Miyama,[12] another chemist of that race, states that the poison is a polyhydrophenol and gives it the name of urushiol. In 1910 we find in Aiton's Encyclopedia (Vol. V), either a new theory or a somewhat imperfect atavism to Burrill's *Micrococcus* hypothesis, when it is said, the poisonous principle "resides not so much in the plant itself as in a minute fungus which lives on the plant." The very latest news I have of the *Rhus* situation, dated 1918,[13] is also from a Japanese and confirms his compatriot's finding that the poison is nonvolatile and is nothing more nor less than the principal constituent of the lacquer, the polyhydric phenol, urushiol. After floundering about among a baker's dozen of rival theories, each smashed to flinders by its successor, it is a comfort to find and lay tight hold upon this firm statement. From this point onward, therefore, we shall regard the problem of *Rhus* poison as solved for all time. As an aside, I may confess, that personally, but secretly, mind you, I fully expect some paper to appear in a year or so that will knock all previous findings into a cocked hat.

However that turns out, I would not fail to record that my experience in looking through the *Rhus* literature, has warmed my heart toward the chemists. Formerly, to my perhaps obscured vision, they appeared to be masquerading as exact scientists, but now that things are clearer to my eyes, they seem like brothers, since it proves that their science is as fully and as delightfully inexact as the various branches of my own beloved natural history.

This parallelism can be carried further, for the chemists, like the biologists, have also fallen into the pitfall of nomenclature. The older chemists steered clear of this trouble by contenting themselves with enumerating various properties of the substances they investigated. This method was not exciting enough for the newer school, however, and names were invented for each new or supposedly new thing found. Like the earlier biological nomenclators, each chemist seems to have named things pretty much as he pleased, a practice naturally giving rise to a beautiful array of names for the same thing. For instance, fourteen nominally distinct acids have been reported from *Rhus* sap, a number surely more than double the tale of different acids really present. Again we read that a Japanese chemist called the alcohol-soluble part of lachurushic acid and the alcohol-insoluble part, diastatic matter; and that a little later a French chemist called the same things laccol and laccase.

Without going into detail about substances merely described, such as a "nitrogenous substance having no oxidizing properties," we may list the definitely named constituents that have been reported from *Rhus* sap. The acids, for instance, are: acetic, gallic, Japanic, mucic, oxalic, palmitic, rhustannic, sebacic, succinic, tartaric, toxicodendric, usihic, urushic, and urushinic. Other things are: acrolein, fisetin, myricetin, palmitin, pectin, phytosterin, quercetin, gallo-tannin, laccol, laccase, rhamnose, myricyl alcohol, ceryl alcohol, methane, hexane, octane, pyrocatechol, toxicodendrol, urushiol, verniciferol, polyhydrophenol, dihydroxyphenol, besides resins, gums, waxes, alkaloids, enzymes and glucosides.

Modes of Infection with Rhus Poison.—With all this array of portentously named elements it is no wonder that almost every one finds something in the sap of poisonous *Rhus* that is not good for him. But to return to more serious ways and to our sap it may be said that the sap of *Rhus vernix* (and that of poison ivy is similar) as it flows from a cut in the bark is a thick yellowish-white, sticky emulsion, which upon exposure immediately begins to darken, finally becoming black. The juice has a peculiar sweetish odor and an acrid taste, and from it a varnish apparently identical with Japanese lac can be prepared. Refined to its purest state the actual *Rhus* poison is a powerful escharotic, severely blistering living skin; it is not a caustic, however, as it produces no escharotic effect on the skin of a corpse. The poison is present in the juice of the plant, whether in root, stem, leaves, or immature fruits, but is said not to occur in fully ripened fruits.

From a Nonvolatile Poison.—The commonly accepted theory of Rhus poisoning is that actual contact of the skin with some of the sap or some part of the plant containing the poisonous principle, is necessary. This opinion is not unanimous, however, and much discussion has centered round the theories as to modes of infection, a review of which will, I hope, prove interesting.

The most common ways of getting ivy poisoning are: accidentally brushing against the plants, casually plucking the leaves or breaking twigs with the fingers, coming in contact with broken roots in such operations as transplanting other plants, and in clearing land, plowing, and gardening. Bathers often get poisoned, especially those undressing in thickets, or taking a swim in streams bordered by luxuriant vegetation, where the poison ivy is apt to occur. Woodcutters often acquire the infection in the course of their regular business, and workers about sawmills are poisoned by vines brought in on logs, sometimes after they have lain in the yard for weeks. Numerous cases have their origin in haying operations, or in harvesting crops like corn, in which poison ivy may grow up to a considerable height in one season; and the danger does not pass with the harvest, for cases are recorded of men being poisoned when taking hay containing ivy from mows in the winter time.

Among less common occurrences that result in poisoning are: the cutting of sticks by boys from the poison sumach, for use in playing hockey and ball; the gathering for decorations of the leaves of this plant, which are among the most brilliant in autumn; and handling of herbarium specimens, sometimes when several years old. One physician states he was poisoned through rubber gloves, as the juice of the plant combined with the rubber and stained it through. A case has been reported to me of poisoning from the ashes of burned poison ivy plants.

Poisoning has resulted in several ways also from lacquer imported into this country. Romyn Hitchcock[14] notes that a piano manufacturer, trying lacquer in his establishment, was forced to give it up on account of the effects upon the workmen. Dr. Millspaugh[15] records a similar termination of an

experiment in the use of lacquer in a boot varnish, which poisoned all who worked with it. Paperhangers also have been poisoned by lacquer on imported embossed wallpapers.

Internal poisoning by *Rhus* toxin has resulted from such actions as chewing poison ivy leaves, eating the green fruit, drinking supposed sassafras tea made from roots among which those of *Rhus* were mixed, eating the root of a poisonous sumach by mistake for sarsaparilla, and from overdoses of tincture of *Rhus toxicodendron* and of homeopathic *Rhus tox* pellets.

The cases thus far discussed involve direct contact with the poison of *Rhus* either in the plant itself or in a product. There are in addition two very interesting classes of causes of *Rhus* poisoning, namely, by indirect contact, and the much disputed infection without contact, either direct or indirect.

It is well known that clothing, shoes, and the like on which *Rhus* sap has dried may cause sumach poisoning even for months afterwards, and tools that have come in contact with the sap are equally dangerous. Characteristic ivy poisoning has been known to develop on a man's thigh under a pocket in which was carried a knife that had been used in cutting a sumach plant. Even remedies, such as sweet oil, used to alleviate a case of poisoning, have produced a new case of infection, when oil from the same bottle has afterward been applied to the body for another purpose.

Handling any animal that has been brushing through poisonous *Rhus* plants is dangerous, and several cases in which human beings have transmitted it to each other are on record. Persons of greater immunity to the poison thus transfer it to the more susceptible, and one of the few fatal cases of *Rhus* poisoning reported was in this way given to a boy by a family servant who was not himself affected. Thus under certain circumstances even a handshake is dangerous.

The question as to whether *Rhus* poisoning is ever contracted without actual contact, either direct or indirect, with the poisonous principle is one concerning which there is a mass of evidence on both sides. In this discussion the point at once comes up as to whether the active poison of these plants is in any degree volatile, a supposition controverted by most of the modern evidence. But letting the settlement of this question rest for a moment, I will discuss the other methods by which it has been supposed poisoning might occur without actual contact.

Thus so long as it was held that the poisonous principle of *Rhus* was a gas it was perfectly natural for people to make statements such as the following quoted from Asa Christy,[16] 1829, in regard to *Rhus vernix:*

"The far-famed bohon upas (if actually existing) does not possess qualities of a more remarkable nature, for there is an atmosphere generated around these plants, which by simple inhalation, excites its peculiar inflammatory action in the system, attended by all its disagreeable concomitants."

Even today many persons firmly believe that they may contract the poison merely by passing near some of these poisonous plants. Modern evidence, however, does not favor this view, for it has been shown[17] that the pollen, plant-hairs, and cork-cells of the bark of these plants, the only parts likely to be carried by the wind, are non-toxic. The possibility of insects carrying minute quantities of the poison should not be overlooked in considering cases of poisoning at a distance.

The poison can be carried by smoke from burning sumachs, but exactly how it is done is not generally understood. As a sample of one of the earlier statements on this point, I quote, including some of his introductory words relating to *Rhus vernix*, the following from "An Account of the Poison-Tree in New England," by P. Dudley,[18] written January, 1721, for the London Philosophical Transactions: "The inside of the wood is yellow and very full of juice as glutinous as honey or turpentine; the wood itself has a very strong unsavory smell, but the juice stinks as bad as carrion. It poisons in two ways, either by touching or handling it, or by the smell, for the scent of it when cut down in the woods, or put on the fire, has poisoned persons to a very great degree. * * * A gentleman in the country was swelled up for several days with the smoak or flame of this wood. * * *" W. Sherard gives in the same volume, "A farther account of the same tree" (P. 217), in which he says: "When laid on the fire, of 5 or 6 persons sitting by it, some will fall a swooning, fainting or yawning, and continue so for several days, some but a few hours, and others of the company are not at all affected."

By experiment it has been learned that *Rhus* poison can be carried by unfiltered but not by filtered smoke from the burning plant, the conclusion therefore being that the active principle is mechanically carried by soot particles. Distribution of the poison by smoke may assume considerable importance, for as one of the consequences of forest fires, all the members of several families have been thus infected by *Rhus* poison.[19]

From a Volatile Poison.—Now, for what possibly is the most debated point in the whole of the exceedingly controversial *Rhus* discussion, namely, the volatile or nonvolatile character of the active principle. Practically all of the more scientific investigations of the subject have resulted in decisions that the poison is nonvolatile. For one I do not believe evidence on the other side has been given due weight. For instance, we have the deliberate statements of such well known scientists as Dr. John Bachman and Dr. Charles E. Bessey, both very susceptible to the poison, and who therefore took the greatest precautions to avoid poisoning, that they were nevertheless poisoned by plants handled in their presence, but entirely by other people. These and other bits of testimony to the same effect might be explained away by some of the indirect transferences of ivy poison, such as I have previously mentioned, did not the place where the poison took effect in several cases give such suggestive evidence of volatility of the toxin. For instance, of the case of Dr. Bessey, in which an assistant had brought in a vasculum some poison ivy plants, warning the doctor not to touch the box or its contents, Dr. Bessey himself says that he merely leaned over the vasculum directing what specimens to save and was poisoned only on the parts of his hands and face that were directly over the box. He further says:[20] "I do not see how any

one can escape from the conclusion that that which poisoned me so severely and so peculiarly was volatile enough to be carried up (apparently in straight lines) in the warm air which escaped from the tin collecting box (vasculum) when opened in my study. In this case there was no contact on my part with the poison ivy, nor with any other plants in the vasculum. I had been poisoned too often to be careless when warned by my assistant. I am not denying the truth of Dr. Pfaff's conclusion that there is a nonvolatile poisonous oil in the poison ivy. I am forced to conclude that there is a volatile poison also in the plant."

A very similar case is recorded by Dr. Richard E. Kunze,[21] who at the time was experimentally attempting to infect with the poison two supposedly immune persons. He states: "With a pair of forceps I took a leaflet from a glass jar * * * and repeatedly rubbed it across the * * * forearms of both parties. * * * To inoculate, I had to reach across the table on which stood the open jar, the mouth of which was directly under my chin. The inoculated escaped scot-free, and the operator paid the penalty. The emanations while bending over the jar produced a circular patch of vesicles three inches in diameter, corresponding with the mouth of the vessel mentioned."

Romyn Hitchcock, formerly of the National Museum, opened a bottle of Japanese lacquer that had been kept stoppered for years, had a feeling as of a warm breath in his face, accompanied by a suffocating disagreeable odor, and had an eruption on his face in three days.[22]

Acree and Syme,[9] who made one of the most thorough modern investigations of *Rhus* poison, note when a bottle containing ether-extract of poison-ivy leaves was opened, "there appeared to be an escape of vapor, and a nauseating odor * * * pervaded the atmosphere. Some days later irregular red patches appeared on [the worker's] face, though a mask of cotton cloth was worn during the work." (pp. 302-3.)

The writer is the more inclined to take the affirmative side of the volatility argument because he has experienced the feeling of the vapor from the sap of poison ivy, and after learning the acrid, irritating nature of the emanation, has on several occasions thus had the first warning that he had exposed himself to infection.

Dr. D. P. Penhallow[23] brings up this point in an account of his experiences in Japan. During a four years' residence in that country he was poisoned more than a dozen times. "One very well-defined picture of its action," he says, "was that after a few experiences it was always possible for me to ascertain whenever I came into an atmosphere charged with the poison, as in a close room. This was manifested by a well-defined, though not strong acid taste in the mouth, and a slight, somewhat acute pain directly between the eyes." Dr. Penhallow stirred and smelled some lacquer and had his face badly poisoned.

Evidence that there seems no good reason to question, therefore, indicates that under certain circumstances poisonous species of *Rhus* and preparations made from them have a poison which appears to be volatile, or that is poisonous in so finely divided a state that the particles can be carried by a volatile constituent of the sap, which in effect amounts to the same thing.

Is There Immunity to Rhus Poisoning?—From the foregoing review of the means by which *Rhus* poisoning may be acquired, it would seem that the possibilities are so varied that no person could have the good fortune to evade all of them. However, there is a widespread belief that some persons are immune to the poison. Many of these supposed immunes have sooner or later discovered to their sorrow that hypothetical immunity is a poor dependence. Some have marvelous good fortune, however, as did Peter Kalm, the early botanical explorer of America, who tested poison ivy in every way, even to the extent of squirting some of the juice in his eye, without bad effects.

However, experiment has demonstrated that probably no person is entirely immune to *Rhus* poison. In a test of this kind, Dr. Stanley Coulter experimented with more than 40 species of the plants of Indiana, reputed to be poisonous by contact. In these tests, mere handling of the plant was first tried; then in the cases of persons not affected by this process, the leaves were well rubbed in on the forearm until serum and at times blood exuded, the juice of the plant and the serum then being allowed to dry on the arm. Under this treatment no person escaped ivy poisoning and poison ivy was the only plant tested that did affect every person upon whom it was tried.[24] This result was later corroborated in California by Dr. Edward Von Adelung, who tested 12 persons who believed themselves to be immune, and found that not one was. These trials indicate universal susceptibility to *Rhus* poison.

Symptoms of Rhus Poisoning.—Now that the cause of *Rhus* poisoning, the modes of infection, etc., have been discussed, we may proceed to consider the malady itself. It is often discussed under the names of dermatitis venenata or dermatitis toxica, though these terms apply, not to *Rhus* poisoning alone, but to all external inflammations caused by irritant poisons. This particular dermatitis has been called erysipelas a rho, erythema venenosa, and among the Japanese, urushi rabure, meaning lacquer infection. It is perhaps best known in English (if we may say so) as *Rhus* dermatitis. The first description of the malady can be found in a Chinese work called Ping-yuan-hon-lun, date of about 605 to 609 A. D., and later in a Japanese document with the name of Wamyo-ruiju-sho of the relatively modern date of 923 to 930 A.D.

The symptoms of *Rhus* dermatitis in the order of their appearance are: redness of the skin, itching, swelling, and the formation of numerous small elevated vesicles or blisters, or larger eruptions of the same order known as blebs. The itching of *Rhus* dermatitis, according to the writer's experience, is specific, and from its peculiar character will be recognized immediately upon recurrence after it has once been felt. The vesicles at first are filled with a clear fluid, which later becomes yellow, like pus; if not reduced the vesicles break and the pus dries, forming a yellow incrustation. As the malady passes, desquamation of this crust ensues, leaving the skin very tender and of a florid red color. From this stage to the normal appearance

of the skin requires but a short time. In other words, "the eruption is an acute, simple inflammation of the skin, inclining always to spontaneous recovery."

The severity of a case of *Rhus* dermatitis depends very largely on the area involved. When the face is badly affected, the eyelids become tumefied and closed; occasionally the whole body is poisoned and becomes greatly swollen. In the worst cases, probably due to interference with the functions of the skin, there are constitutional symptoms, including a sympatheic fever, which may be so severe as to produce delirium. A few cases of the loss of hair and nails have been attributed to *Rhus* dermatitis, and extremely few of death.

In internal poisoning by *Rhus* toxin, the symptoms —inflammation of the mucous membranes, coughing, drowsiness, vomiting, diarrhea, convulsions, and delirium, with hurried respiration and weak pulse, are more alarming and recovery much more slow.

Recurrence of the Dermatitis Without Reinfection.—Two interesting speculations connected with *Rhus* poisoning relate to recurrence of the trouble without reinfection, and to autoinoculation, a process by which a malady is carried in the circulation to other parts of the body than that originally infected. Part of the cases which autoinoculation is invoked to explain are disposed of by the fact that poisoning often takes place through clothing, and the *Rhus* sap directly reaches a part of the body deemed protected. Another portion of these cases may be explained by unconscious transfer of the toxin by the hands from infected to noninfected parts of the body. There seems to be no sound reason for believing in the autoinoculation theory. The spread of the poison by serum from the vesicles is also believed to be impossible; observations having a contrary indication bring more rationally explained by the transfer with the serum of minute quantities of the original poison, which are amply sufficient to start a new eruption.

As to recurrence of *Rhus* dermatitis without reinfection there are profound differences of opinion. Numerous physicians have recorded such cases, but investigators of the experimental school have been inclined to deny them as absurd. In this instance as in others my position is that we should not give to theory, no matter how logical, nor to thinking, no matter how rigorous, equal consideration with apparently unimpeachable observations.

As an entering wedge for the introduction of testimony relating to recurrent cases of *Rhus* poisoning, I may cite my own experience that an old and apparently cured eruption can break out afresh. If this can happen after a lapse of weeks, it does not require great credulity to believe that it can do the same after a twelvemonth. The late Professor W. W. Cooke, a particularly methodical, careful and logical man, told me on various occasions of his own personal experience with a case of ivy poisoning that was recurrent for a period of several years. To mention only one or two of the unequivocal recorded cases of recurrence, I may cite that of Thomas Meehan,[25] the noted horticulturist, who had a *Rhus* dermatitis recur for a long series of years, during several of which he lived entirely in the city where there was almost no possibility of reinfection. In the *Ottawa Naturalist* for 1912, is cited[26] a case of poisoning on the foot (contracted when bare) which recurred for 7 years without possibility of infection. The early American naturalist, Dr. Barton, of Philadelphia, personally experienced a recurrent case of *Rhus* dermatitis, one of the periodical eruptions of which occurred while he was in Europe.[27] The regular annual occurrence of these renewals of *Rhus* poisoning, which has been scoffed at as a superstition, to my mind, not only does not weaken the case for recurrence without reinfection, but on the contrary, materially strengthens it, for it is highly improbable that new infections would be experienced at the same time in each of a long series of years.

Remedies for Rhus Poisoning.—The properties of the *Rhus* toxin, the modes of infection, the symptoms of the dermatitis and related matters all lead up to one main interest—that of remedies. The most striking feature of this section of *Rhus* literature is the extreme number and diversity of substances recommended for the treatment of the poisoning. Obviously one cause contributing to this result is the variety of theories that have been held as to the nature of the toxin. When the poison was thought to be an acid, alkalis naturally were used in neutralizing it; next when it was considered due to bacteria, germicides were in order; when a resin, solvents were called for; and as a glucoside, serum therapy with its antibodies was suggested. I notice, moreover, this is all good allopathic doctrine; the homeopaths who believe *similia similibus curantur* have a different set of curatives.

Not only did the theories call for a wide range of remedies, but physicians empirically came to favor a variety of curatives, each doctor, almost, having his pet treatment. In illustration of this variety, I will quote the opinions of a number of physicians.

Dr. W. E. Brandt[28] in the MEDICAL RECORD reports on various remedies, but declares a saturated solution of hyposulphite of soda externally, in severe cases, internally, is the best he knows, and in later pages of the same volume Dr. J. M. Ward announces chlorinated soda or Labarraquès solution as his favorite.[29]

Dr. Richard E. Kunze,[30] who himself was poisoned every year for 29 years and trying new remedies all the time, finally settled on pure acetic acid as the best.

Dr. C. H. Humphreys[31] states that sulphate of zinc affords speedy and certain relief, while Dr. A. E. Baldwin,[33] of California, after trying a number of treatments, asserts that: "Carbolic acid in solution and as an unguent is the only remedy of value."

Dr. Thomas Giffard[33] states that he used fluid extract of *Lobelia inflata* for 42 years with success, and Dr. S. A. Brown,[34] a naval surgeon, reports that bromine in olive oil was used successfully in over one hundred cases.

Dr. J. W. Hawley[35] states that spirit of niter cures in 24 hours, every time, and that he has used tincture of *Ledum palustre* for 20 years with unvarying success.

H. N. Hohnes,[36] in citing a modern remedy for ivy poisoning, says that the only satisfactory one is a solution of potassium permanganate, applied hot.

Dr. T. J. Daniel[37] says that calomel in lime water has never failed, and that a solution of sulphate of quinine in water is a specific.

One physician reports a trial of aulactotherapy; a cow was fed poison ivy leaves and her milk was imbibed the next day; this was followed by apparent immunity for the rest of the summer. This method was tried on a child also with success.[38] Another doctor who used nitrate of silver in his practice, himself became poisoned, and remarks:[39] "I did not like to black my face, although I had frequently blacked my patients'."

So it goes: one man uses one thing, another something else. I have tabulated the distinct substances recommended in the literature and those I have learned of otherwise, and so far have the following totals:

Recommended for preventing *Rhus* poisoning... 19
Recommended for internal use in treatment of *Rhus* poisoning 27
Recommended for external use in treatment of *Rhus* poisoning 198

Eliminating duplications, there are many more than 200 different substances or processes that have been used in the treatment of *Rhus* dermatitis. Various combinations of these also are used so that the total number of treatments of *Rhus* dermatitis that could be differentiated probably runs to several hundred.

In this connection it has been very appropriately remarked that all of the three kingdoms, Animal, Plant, and Mineral, have been laid under contribution to pay tribute to the Tyrant, *Rhus*.

Recommended for preventing Rhus poisoning, 19:

To be used before exposure (4): Coating exposed parts of body with sweet oil, cottonseed oil, grease, or soapsuds, dried on.

To be used internally (4): Tincture of *Cypripedium* (lady's slipper), tincture of *Rhus toxicodendron* (poison ivy), chewing leaves of *Rhus toxicodendron* (poison ivy), milk of cow fed on poison ivy.

To be used after exposure (11): Washing with soap and water, hot soapsuds, alcohol, ether, turpentine, gasoline, solution of sodium bicarbonate, solution of potassium iodide, solution of magnesium sulphate, solution of carbolic acid, rubbing with moist earth.

Recommended for internal use in the treatment of Rhus poisoning, 27:

Tinctures or fluid extracts of the following plants (12): Sweet fern (*Comptonia asplenifolia*), snakeroot (*Aristolochia serpentaria*), pasque flower (*Pulsatilla hirsutissima*), aconite (*Aconitum uncinatum*), spicebush (*Benzoin æstivale*), hura (*Hura brasiliensis*), poison ivy (*Rhus toxicodendron*), poison sumach (*Rhus vernix*), pipsissewa (*Chimaphila maculata*), yellow jessamine (*Gelsemium sempervirens*), belladonna (*Atropa belladonna*), bryony (*Bryonia dioica*),

Other remedies derived from the vegetable kingdom (5): Strong coffee, morphine, quinine, chewing leaves of poison ivy (autotherapy), or of five-leaved ivy, or Virginia creeper (*parthenocissus quinquefolia*).

Remedies consisting of chemical elements or preparations based on them (8): Fowler's solution of arsenic, sweet spirit of niter, potassium iodide, tincture of iron, sodium bromide, sulphur, calomel, Epsom salts and other saline purgatives.

Miscellaneous remedies (2): Copious drinking, soot suspended in milk.

Recommended for external use in the treatment of Rhus poisoning, 198:

Tinctures, infusions or poultices of various plants 70
Other plant products.....17
Acids 10
Salts of various elements.....44
Other chemicals 22
Emollients of various origin.....11
Various substances of animal origin.... 8
Other materials and processes.....16

Tinctures, infusions or poultices made from following plants (70): Fungi: Family Agaricaceæ: Field mushroom (*Agaricus campestris*).

Spermatophyta: Family Liliaceæ: Lily-of-the-Valley (*Convallaria majalis*); false hellebore (*Veratrum viride*); soap-root (*Chlorogalum pomeridianum*), mashed-up bulbs.

Family Orchidaceæ: Lady's slipper (*Cypripedium* spp.).

Family Salicaceæ: Cottonwood (*Populus* spp.).

Family Myricaceæ: Sweet fern (*Comptonia asplenifolia*).

Family Fagaceæ: White oak (*Quercus alba*), bark; black oak (*Quercus velutina*), bark; chestnut (*Castanea dentata*), leaves.

Family Urticaceæ: Richweed (*Pilea pumila*), bruised stems.

Family Aristolochiaceæ: Snakeroot (*Aristolochia serpentaria*).

Family Phytolaccaceæ: Pokeweed (*Phytolacca decandra*), infusion of root.

Family Nymphaeaceæ: Waterlily (*Castalia odorata*); American lotus (*Nelumbo lutea*).

Family Ranunculaceæ: Bugbane (*Cimicifuga racemosa*); wild peony (*Pæonia brownii*).

Family Lauraceæ: Sassafras (*Sassafras officinale*), infusion of roots; spicebush (*Benzoin æstivale*), infusion inner bark; camphor (*Cinnamonum camphora*), infusion wood; spirit.

Family Papaveraceæ: Bloodroot (*Sanguinaria canadensis*), juice or infusion of roots; celandine (*Chelidonium majus*), infusion.

Family Crassulaceæ: House leek (*Sempervivum tectorum*), infusion of leaves.

Family Hamamelidaceæ: Witch hazel (*Hamamelis virginiana*), extract.

Family Leguminosæ: Sweet clover (*Melilotus* spp.); bean (*Phaseolus vulgaris*), fresh leaves.

Family Rosaceæ: Raspberry (*Rubus* spp.), fomentation of leaves; California holly (*Heteromeles arbutifolia*), decoction.

Family Euphorbiaceæ: Croton (*Croton tiglium*); spurge (*Euphorbia* spp).

Family Anacardiaceæ: Poison ivy (*Rhus toxicodendron*), tincture; poison sumach (*Rhus vernix*), varnish from; cashew nut (*Anacardium occidentale*).

Family Aquifoliaceæ: Black alder (*Ilex verticillata*).

Family Celastraceæ: Bittersweet (*Celastrus scandens*), infusion.

Family Sapindaceæ: Buckeye (*Æsculus californica*).

Family Balsaminaceæ: Touch-me-not (*Impatiens pallida*), stems; Touch-me-not (*Impatiens biflora*), juice.

Family Rhamnaceæ: Buckthorn (*Rhamnus californica* and *R. purshiana*).

Family Garryaceæ: Bear brush (*Garrya* spp.).

Family Ericaceæ: Labrador tea (*Ledum palustre*); manzanita (*Arctostaphylos* spp.), decoction.

Family Loganiaceæ: Yellow jessamine (*Gelsemium sempervirens*), fluid extract.

Family Asclepiadaceæ: Milkweed (*Asclepias* spp.), juice.

Family Verbenaceæ: Vervain (*Verbena hastata* and *V. urticifolia*).

Family Labiatæ: Horse balm (*Collinsonia canadensis*), leaves and stalks; Rosemary (*Rosmarinus officinalis*), juice; mountain mint (*Pycnanthemum* spp.), leaves; pennyroyal (*Hedeoma pulegioides*), leaves and extract.

Family Solanaceæ: Nightshade (*Solanum dulcamara*), leaves and berries; jimson weed (*Datura stramonium*), leaves; belladonna (*Atropa belladonna*), extract.

Family Scrophulariaceæ: Foxglove (*Digitalis purpurea*), infusion.

Family Plantaginaceæ: Ribgrass (*Plantago lanceolata*), leaves.

Family Rubiaceæ: Buttonbush (*Cephalanthus occidentalis*), infusion.

Family Caprifoliaceæ: Bush honeysuckle (*Diervilla lonicera*), infusion; elder (*Sambucus canadensis*), decoction of bark.

Family Cucurbitaceæ: Bryony (*Bryonia dioica*), tincture.

Family Lobeliaceæ: Indian tobacco (*Lobelia inflata*), tincture, infusion leaves.

Family Compositæ: Boneset (*Eupatorium* spp.); tarweed (*Grindelia squarrosa, G. hirsutula, G. robusta*), fluid extract; goldenrod (*Solidago canadensis*), chewed-up roots; everlasting (*Antennaria* spp.), infusion; marigold (*Calendula officinalis*), juice; arnica (*Arnica montana*), tincture; wild lettuce (*Lactuca canadensis* and *L. "elongata"*), leaves and stems.

A total of more than 70 species of 37 families.

Other plant products: Alcohol (including brandy and whiskey), coffee, cocaine (glycerite and oleate of), eucalyptol, guiaicol, ipecac, laudanum, also morphine sulphate, laurel water, quinine, rice powder, starch, tannin, turpentine, elderflower water, rosewater, oil of bergamot.

For the treatment of affected eyes only, the following have been used: Eye bright (*Euphrasia*), Eserine, an alkaloid from the Calabar bean (*Physostigma venenosum*).

Acids: Acetic (also vinegar), benzoic, boric, carbolic (also glycerite of carbolic and phenol sodique), citric, hydrocyanic, lactic, oxalic, salicylic, sulphurous.

Salts of various elements: Aluminum acetate, aluminum hydrate, bismuth subnitrate, bismuth subgallate, bromine, calcium chloride (as limewater and chlorinated lime), calcium sulphite, carbon, in the form of plumbago, copper sulphate, hydrogen peroxide, indium, iodine, iron chloride, iron perchloride, iron sulphate, iron subsulphate, lead oxide, lead subacetate, magnesium carbonate, magnesium sulphate, mercuric chloride, mercuric subchloride, mercuric iodide, mercuric oxide, mercuric peroxide, potassium citrate, potassium carbonate, potassium chlorate, potassium chloride, potassium hydroxide, potassium nitrate, potassium permanganate, silver nitrate, sodium borate, sodium carbonate, sodium bicarbonate, sodium chlorate, sodium chloride, sodium hydroxide, sodium sulphite, sodium thiosulphite, sulphur, zinc oxide (also benzoated), zinc silicate, zinc sulphate.

Other chemicals: Acetanilid, ammonia, ammonium acetate, ammonium chloride (salammoniac), ammonium hydrochlorate, ammonium ichthyosulphonate (ichthyol), antiphlogistine, antipyrin, aristol (dithymol diiodide, CHI_3), benzol, chloroform, chloral hydrate, collodion, creolin, formol, gasoline, iodoform (thymol iodide), lysol, nitrous ether, resorcin, salol, thymol.

Emollients of varied origin: Cold cream, cosmoline, cottonseed oil, cream, diachylon, glycerin, lanolin, lard, linseed oil, olive oil, petrolatum.

Various substances of animal origin: The poisonous element of the sting of the honeybee (*Apis*); human urine; sepia, a preparation from the ink of cuttle fishes; flesh and juices of great spider crab (*Macrocheira kaemferi*); milk from cow which has been fed poison ivy, serums containing antibodies, sour milk, buttermilk.

Other materials and processes: Baths and bathing in hot water, hot water and soapsuds, sea water, thermal springs, Russian baths, Turkish baths, cold water; applications of ice, applications of heat—either dry or by bran poultices; applications of earth, blood letting, blistering, with plasters, etc., burned leaves and wood of the plant (*Rhus*) rubbed on, either plain or in lard; burning old rags on a rusty hatchet and collecting the "dew" (grease?), which appears for use in treating poisoned areas; soap, especially home-made soft soap; let it alone.

The last process brings to mind the remark of a Brooklyn doctor: "Multiply the number of years represented by my gray hairs by two and you will not come far from the number of personal tests which I have had an opportunity to make of various remedies from let it alone to sour buttermilk. Both are excellent."

It has often been asserted, and seems to be a fact, that in the practice of medicine the multiplication of remedies for any malady is in direct proportion to their inefficiency. Judged by this criterion, the remedies for *Rhus* dermatitis, being so extraordinarily numerous, must accordingly have an unusually low average value. As previously mentioned, *Rhus* dermatitis is self-limited with a tendency to spontaneous recovery, usually running its course in 10 to 14 days. Undoubtedly many alleged cures owe their reputation to the fact that they have been used just as the malady was abating naturally. The chief elements of a rational treatment seem to be thorough cleansing of the infected surface with hot water and soap, and applications (in the most advanced practice of alkaline washes) to relieve the subjective sensations of itching and burning—in other words, Nature must do the healing, but we can aid her a little.

As a matter of interest it may be well to present in detail the methods of treatment preferred by authors of two of the latest and most scientific contributions to *Rhus* literature. Dr. A. B. Stevens[4] recommends washing with a 2 per cent. alcoholic solution of sodium hydroxide and after ten minutes washing with an 8 per cent. solution of sodium bi-

carbonate, this process repeated three to four times a day.

Dr. I. Toyama [42] gives as his favorite remedy the application of a wash consisting of caustic potash, 1 gram or cubic centimeter, alcohol 30, glycerin 10, and water 60. This reveals the extent of poisoned surface as the resin adhering to skin is turned black. This can be removed by a 1 per cent. alcoholic solution of nitric acid. Now wash thoroughly with soap and water and apply lead acetate as a compress.

The Effects of Rhus Toxin Upon Animals.—Whether *Rhus* poison affects animals as unfavorably as it does man is another of the *Rhus* problems that is in dispute. Dr. J. C. Guernsey[43] states that horses, pigs, sheep and goats eat poison ivy without harm. Horsfield[27] says the same of horses, cows and sheep, while in a recent study of the subject it is stated,[44] with reference to Western poison oak, that: "On the ranges the leaves and berries are readily eaten by sheep, goats and horses, but not by cattle, as far as could be ascertained by observation and numerous inquiries."

Dr. J. Bommer[45] asserts, however, that animals, presumably cattle, are as badly affected as humans, the lips becoming swollen, stiff and scabby so that they cannot eat. He records curing them with a solution of ipecac.

Dr. Joseph Hunt[40] reports that: "It is said that * * * dogs exposed * * * die with dilated pupils, without coma or convulsions, but with general swelling of the body." (p. 395.)

Usefulness of Poisonous Sumachs.—With the record of causing inconvenience and suffering to thousands of people every year, and even in extreme cases of causing death, it may seem paradoxical to speak of the usefulness of the poisonous species of *Rhus*. Yet the use of the *Rhus* toxin in medicine is very extended, and, according to many doctors, very important.

In the first place, it is used by homeopaths for immunizing people against Rhus poisoning, and in the treatment of the dermatitis, both by internal administration of an attenuated tincture.

In general medical practice it has been credited with the following therapeutic qualities: Alterative, antiseptic, antispasmodic, diaphoretic, diuretic, incitant, laxative, narcotic, tetanic, and as a general stimulant for the nervous system. It has been used in the treatment of at least 41 disorders and diseases of the human body, and for a number of them is said to be the most valuable remedy known. One doctor, convinced of the value of the active principles of poisonous sumachs, complains that the substitution of Virginia creeper leaves for those of *Rhus toxicodendron* is a deception on Physic.[46]

Human Disorders and Diseases in the Treatment of Which Rhus Toxin Has Been Used: Abscesses, amaurosis, bronchitis, bruises, burns, carbuncle, cardiac hypertrophy, catarrh, cellulitis, cerebral engorgement or irritation, chilblains, cyclitis, diarrhea, eczema, erysipelas, erythema, herpes, influenza, iritis, itch, nervous prostration, neuralgia, palpitation of heart, paralysis, pemphigus, pneumonia, pulmonary tuberculosis, *Rhus* poisoning, rheumatism, scarlet fever, sciatica, septicemia, spinal anemia, spinal irritation, sprains, stings of insects, typhoid and typhus fevers, ulcers, vertigo.

A gum called doctor gum or hog gum obtained from the poisonous coral sumach is used as an antisyphilitic, astringent, demulcent, emetocathartic, styptic, and vulnerary, and is an important element of the materia medica in the region where this sumach is native.

Among the miscellaneous uses of poisonous sumachs is that recorded by Hughes[47] for the Barbados, where a "cataplasm of new-extracted juice is of service to kill chiggers."

As noted previously, the Western poison oak has some value as forage, and we are further informed regarding this species (*Rhus diversiloba*) that although greatly dreaded by the Cherokees, who endeavor to conciliate it by addressing it as "my friend," it does not seem to injure certain California tribes so much. They even use it as medicine, though sometimes poisoning themselves internally by the practice. They further use the twigs as water sprinklers in sacred ceremonies, and it is also a material for woven fabrics, and its juice, which turns black rapidly on exposure to air, is utilized as an intense black dye for basketry.[48]

Horsfield[27] records also that the branches of *Rhus vernix* once were used, presumably by Eastern tribes of Indians, for flutes, whistles, and calumets or pipes of peace. For these purposes the wood must have been given special treatment to destroy the poisonous principle.

Public Policy Toward Poisonous Sumachs.—To a very limited extent poison sumach (*Rhus vernix*) has been used as a specimen plant for parks, and poison ivy (*Rhus toxicodendron*) for an ornamental vine, for which purposes they are well suited in every way, except for their poisonous properties. I have seen these plants used for both the purposes mentioned in the city of Washington, D. C., and a former chief of bureau of the Department of Agriculture contracted a severe case of dermatitis from a poison sumach in the grounds of that department. The plant has since disappeared.

It goes without saying that specimens of these plants in public places should be removed, and it will repay private property owners to suppress the poisonous species of Rhus, so far as possible. Practicable ways of doing this on a large scale are not yet known. It has been suggested that workmen selected for their comparative immunity to *Rhus* poisoning be employed, and that they be equipped with special heavy clothing and gloves not permeable to the sumach sap, which could be daily steamed and treated with neutralizing chemicals. This method is beyond the means of most property owners, however, and, despite all the precautions proposed is not without danger to the workmen. Simpler means of killing poison ivy plants include covering them with tarred paper, creosoted below, and means adapted to both poison ivy and poison sumach are: Pouring small quantities of concentrated sulphuric acid about each stem, and treating in the same way or spraying the plants with strong solutions of sodium arsenate, say two pounds to 10 gallons of water.

Poisonous Sumachs in Lighter Vein.—A Supposed Property of the Wood: Dudley,[18] in his account of the Poison-tree of New England, records a peculiar belief relating to poison sumach. "My neighbor," he says, "that was so sadly poisoned with handling

it, told me one thing very remarkable, and that is, that when he touched it he plainly perceived it to differ from the other wood that he was throwing into his cart, by its being as cold as a piece of ice; and withal assured me that he could distinguish it blindfolded from any other wood in the world by its coldness."

Pro and Con as to the Effects of Poisonous *Rhus* on Bees: Bigelow[49] reports that "In the New York Medical Repository is an account of a swarm of bees which, having alighted on the branches of *Rhus vernix*, were the next day found dead, with their bodies black and swollen." On the other hand, bees and other insects freely visit the flowers of poisonous sumachs, from which it is reported that domestic bees make an excellent honey.

Terrific Nature of *Rhus* Poison: Dr. James C. White[50] reproduces the following very imaginative account of the *Rhus* toxin: "Bazin, in his "Affections Cutanees Artificielles," says: [Here I translate] I must tell you something of the singular effects produced by two plants which grow in America, the *Rhus radicans* and the *Rhus toxicodendron*. From these trees, if one may believe authors, there is constantly given off an emanation, irritating and poisonous to a very high degree; unfortunate the imprudent who goes to sleep in their shade! his body is soon covered by a vesicular exanthema, with enormous swelling, and at the same time there become apparent general symptoms which assume the form of acute poisoning and of such violence that death follows in a very short time. [Dr. White then remarks:] After this there should be no doubt either as to the existence or habitat of the fabled upas tree."

Susceptibility of *Rhus* Poison: Dr. Thomas Stratton,[51] who records the fact that among the French-Canadians *Rhus vernix* is called "L'arbre à puce," literally "tree of the flea," perhaps with reference to the flea, puce, or pinkish-brown color of the petioles of this plant, further states: "I heard one say that he knew persons who began to swell immediately on seeing it, and others did the same on hearing its name mentioned."

Immunity to *Rhus* Poison: The two sketches here presented related to a supposed male immune who was sufficiently convinced he was not, and to a lady who believed and hoped she was not immune, but in a particular effort she made to become infected was disappointed.

The story of the man is: Up to the age of 20 years, "I was in the habit of showing the boys how I could eat the stems or chew the leaves with impunity; at that time, in the month of January or February, I was chopping down a tree in the woods upon which there was some vine growing. . . . In cutting off the vine . . . and pulling it down it came down over my face and head, and I had a beautiful attack of *Rhus* poisoning a few days afterward. Up to that time I was entirely immune; since then I have had repeated experiences with it." (Bartley[52].)

The case of the lady is as follows: She had been corrected by her uncle for a trifling error, and, deciding that life was no longer worth living, chose for a method of suicide the eating of an apronful of poison ivy leaves. She suffered no unpleasant symptoms whatever. (Kunze[30].)

Profiting Commercially from Knowledge of *Rhus* Poisoning: It is related that in early days in Virginia a slave wallowed in hay containing poison ivy, broke out all over, and became a repulsive sight. He was treated by the best physician in the county for a year without apparent benefit. Though a young, ablebodied slave, he was sold for $300. The buyer sent to the neighborhood store for five cents' worth of bluestone (copper sulphate) and it cured the negro at once. (Wiseman[53].)

A Traveler's Cure of *Rhus* Poisoning: A cure that many might like, but few have the opportunity to try, is thus recorded: The traveler reports that he was poisoned somewhere in California, obtained his first relief by bathing at the Soda Springs of Mt. Shasta, and was finally cured by a plunge in the hot lake at Mammoth Hot Springs, Yellowstone Park (McKee[54].)

POISE OR TRANQUILLITY A NECESSARY CONDITION OF ECONOMIC REPAIR.

THE NEGATIVE OR RESTING PHASE OF MOVEMENT, AS A FACTOR IN CURE.

By J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF PHYSICAL THERAPEUTICS AND DIETETICS, MEDICAL DEPARTMENT, TEMPLE UNIVERSITY.

ONE of the main reasons why medical advice, or any other good counsel, so often fails of its purpose is that the power of the idea or suggestion is negatived by commotion in the receiving cells and structures. The power transmitters often encounter obstacles disturbing the receptors and transformers—they are in positions of disadvantage. Positions of advantage of the apparatus of normal life are frequently jeopardized by commotions, thus the combined functions of adaptation and application fail of their fulfilment.

The state is one of stressful attention or psychic hypertension, of prodigal energizing without the relief of free motion, hence it verges on strain or exhaustion.*

A bridge or viaduct or suitable device is thereupon needed to convey the energy to the points to be energized.

A better simile might be a series of wires well insulated, such as are requird to safely convey the electric or "vital" currents. Poor insulation permits leakage of electric energy, and human energy is a close analogue. Indeed electrophysiology deserves more attention.

The human organism, which resembles a battery, loses a large proportion of its energy content through various sources of divergency, or inadequacy, or nonadaptability.

Or we might picture the situation as a need for suitable synapses, junction areas or fusion points, where energy directed to a group of structures shall merge (energize) into them favorably. Molecular poise is necessary for right receptivity as well as for energy transmission. Overstrained attention is peculiarly disturbing to functional economies; it encourages leakage, makes for mental commotion, confusion, bewilderment, and leads to exhaustion.

Movement in the human body is usually conceived of as active, less or more but not ceasing. Yet movement consists of two phases of equal significance, the active and the negative phase, or the progressive and the resting; also there is an intermediary transition state or poise.

So little attention is accorded this negative or intermediary phase that it deserves remark. Poise is the point of not only morphogenic advantage but equally of functional—mind and body as one (psychosomatic)—advantage.

Poise is an economic necessity; it must be achieved; and since it so rarely is present, deserves to be definitely taught as the primal condition of both health and the repair of health. The most economic means of achieving poise or relaxation, or the zero point from which all movement, mental or physical advances, is by muscle reeducation.

And this training process must begin with a conscious purposive appreciation of the negative phase of movement, the zero mark, as the point of departure for all economic effort. It is not only important to make the right movement but also to cease making the wrong movement. Each should be a clean motor act from nothing to maximum.

All motor energy should be put forth from the phase of complete relaxation, with just enough expended at a time to achieve the purpose—but no more.

In the action of duplex muscle groups, where extensors are balanced by flexors, as in the arm, extension, for example, should begin, proceed gradually and increasingly with no restraint from flexion or the torsion muscles, except to support the limb as required, to the point of fullest tension.

Also in the other movement, flexion, the direction, velocity, force should be exerted with the same careful graduation from zero to maximum, with no extraneous muscle interference. This poise is the necessary condition of exactitude and economy of movement; also, it is the greatest economizer of energy. In a well poised organism, trained spontaneously and with ample varieties of performance, such acts are always thus performed.

Exceedingly few individuals are either so trained or so well poised as to be emancipated from anxiety inhibitions, self-conscious restraint. Hence it becomes of much importance to determine what degree of restraint exists in any instance, and to make due allowance and to supply correctives.

Regulative Movements, Active and Poised as a Tranquilizing, Hence Curative Agency. — The peace, serenity, and comfort which ensues upon mere rest is limited to the release from weari-

*See article by the author, "Psychic-Hypertension; Restoration of Mind Control by Motor Training in Relaxation," International Clinics, 1912.

ness or weakness brought about by too much stress, amounting often to distress. Rest is only desirable or necessary as a compensation or contrast to movement beyond that which is conservative. The equation between movement and rest can be automatically adjusted or compensated only by cellular restitution. After sufficient rest the impulse recurs to move and must be gratified.

Mere inaction is only one phase or degree of restitution; much more is needed to complete energy renewal than mere cessation of movement. So long as one who needs it welcomes the rest, the first stage of renewal is progressing. When inaction is continued beyond the point where weariness no longer persists, another phase of energy renewal begins wherein the need for movement arises imperatively, and this is shown by a desire to stretch, to turn, to perform instinctive or customary movements, also to yawn, and this improves the quality of rest by readjusting the over-stressed parts, by removing pressure on nerves or sensitive areas in muscles and fibrous movement is felt it must be gratified or a state structures. Thus is restitution carried yet one step further. When this instinctive need for of stagnation (stasis) ensues which if carried too far becomes hurtful or damaging.

In order that one shall remain perfectly still, passive, motionless, then must self-repression be consciously exerted. The feelings, the urgings, the tensions demand to be relieved by a motor discharge of the returning tides of energy.

Self-repression (inhibition) when due to any form of anxiety or apprehension is itself a form of wasteful energizing; it is a tiresome effort to keep still and is one of the least agreeable modalities of motion. Anyone can recall how uncomfortable it is to lay upon oneself a mandate to remain perfectly quiet, to make no movement whatsoever. By and by inaction becomes exasperating, produces another kind of stress more difficult to endure, than forcing oneself to the limit of voluntary exertion. In such a case relief by movement is so pronounced as to far outweigh by contrast the extreme of inaction. Hence oftentimes the limitations of movement on the one hand, and of inaction on the other, are followed by an impulse to do the opposite and to a point of inducing an imperative organic need. In each case the secondary effects of over-action in muscles take place, a surcharge of dynamic energy and the formation of sarcolactic acid and other waste products which compels contraction whereby oxidation and release follows.

In a multitude of disordered states the mental and the physical problems are one, or they fuse and urge the reuniting of the common pathways of thought (volition) and movement which these two spheres of effort bring together.

Much useful work has been done of late furnishing explanations of associated mental and physical (psychosomatic) processes and states in terms of organic changes which explain the varying aspects and strivings of mental life.

These researches furnish new light in explaining human behavior, in suggesting and establishing further therapeutic possibilities. Among these aids to understanding are the researches of Jacques Loeb on: "Forced Movements, Tropisims and Animal Conduct." We can only offer a crude restatement of his findings in so far as they bear upon the problems of the urge toward movement and the effects this striving exerts on behavior.

Loeb expresses the opinion that any form of normal conduct is always the result of a series of forced (compelling) movements; that these become the determinants of conduct and that they are not merely present when it is necessary to restore normal position or condition. The author (Jacques Loeb) begins by a survey of the symmetry of animal forms, of phenomena which make it fairly easy to discover the alternation of movement and its significance in animals when this symmetry is interfered with, as well as the variants in the movements which ordinarily tend to preserve the symmetry.

These meager memoranda will serve to show how necessary movement becomes as a means of recovering poise, harmonies, compensations in the actions and reactions of the physical make up (morphology) and the mental functions or attributes (psychology).

So potently do body states influence those of the feelings, emotions, motives, expectant attention or suspense, that we may profitably review some of them. Expression is thus so plainly evidenced by attitudes, positions assumed in lying, sitting, standing, and epecially while in motion. These may be shown locally, confined to some area or part, or on the other hand be writ large on the contours as a whole.

Facial expressions, in particular those of suspense, distress, anxiety, contempt, anger, and the like unlovely phases of emotivity are due to contractures of muscles. Hence the "contorted features," narrowing of the eyebrows, eyeslits, wrinkling of the temporal and cheek muscles, puckering of the lips, drawing down of the corners of the mouth or retraction of lips showing the teeth ("risus sardonicus" *et al.*), also in strained adjustments of the neck and head. So also clutching, clenching, or wringing of the hands, tense raising or lowering of the shoulders, drooping or raising of the chest, and other familiar phenomena indicating suppressed emotion, mental perturbation, or unrest.

These and similar anomalies of attitude when extended to other and larger areas plainly evidence loss of poise; they are the products of contracture and are due to suspense, stress, strained attention.

Upon relief of the contracture there follows release of both physical and also mental stresses. The effect is due to autosuggestion wherein conscious control of the muscles produces mental serenity.

In this connection let me mention some of the occasions when instinctive demands for making active movements arise and we thus give vent to our feelings when in a state of suspense, worry or self-suppression. We then naturally obey the impulsion to do something; almost any outlet to movement brings comfort. We wish to cry out, to scream, or shed tears, or we walk, pace up and down, gesticulate, throw our arms out or about,

or merely make grimaces. The state is one of generalized or poised over-tension, an equalized push and pull, combined flexion and extension, hence a state of contracture. It may be the action is an extreme push or a pull, one or the other. When such a state of poised tension exists the performing of almost any movement relieves. When to push or to pull becomes imperative, ease is afforded by doing the opposite. After long protracted self-suppression there ensues fatigue; comfort, however, is found in quick, purposeless gestures, throwing the body or head backward or forward; when the breath has been suspended relief is found in sighs, yawns, groans or noisy weeping, sobbing, or these are combined in convulsive movements, "hysterics."

Indeed, such relief is not only desirable, but when the emotional strain has been too great, it becomes mandatory. If resolutely suppressed, disaster may follow:

"Home they brought her warrior—dead.
She nor wept nor uttered cry;
All her maidens watching said,
'She must weep or she will die.'"

So indeed death would have come had not at last:

"Rose a dame of ninety years
Set his babe upon her knee,
Like summer tempest came her tears,
'Sweet my child I live for thee.'"

So much for the sudden compulsion to seek easement by action under acute disturbances. Should the stress, suspense, or self-repression be protracted over long periods the bruised spirit —in one who is wise—seeks balm or surcease by setting about any one of a multitude of active occupations and finds tranquillity or surcease in busy enterprises. The muscular movements afford quite as much restitution as does the mental distraction. This state of perturbation in the Oriental is met by creating an atmosphere of quietism.

Now, let us consider some occupations which prove suitable for adults, noting why they induce serenity. There are multitudes to choose from, in accord with taste, previous training or familiarity. First of all is a reverting to primitive free types of movement, of industry or of childhood play, anything which is capable of sustaining interest. Among these may be mentioned domestic or household work, gardening, floriculture, digging, pruning trees or shrubs, playing on musical instruments, caring for domestic animals, riding a horse, a bicycle, rowing a boat (a wide punt on quiet water is no end of a resource), paddling a canoe, especially heading up against a tide or wind. Great are the resources of camping out, the infinitude of pleasing struggles to secure those comforts which thus are made to flow round the now perturbed one like a placid tide, unnoticed and unappreciated during every-day life. So of simple games of competition, croquet, tennis, golf, billiards, bowling, throwing and catching a ball, and the like.

No better agency for sustaining interest is known than carpentry, metal working, any form of construction. Here competition can be with one's-self to produce something increasingly worth while. So of art forms, modelling in clay, carving in wood, sketching, water colors, pastels or mere pencil or charcoal.

Perhaps I can present the topic under consideration no better than by citing some illustrations of the more obvious means of inducing calm by means of motion. Later I will sketch out my ceremonial of relaxation devised as a routine measure to secure a state of mental poise from whence to proceed as the starting point for achieving systematic conscious control.

Voice training has long been used to steady overwrought nerves. The late S. Weir Mitchell frequently directed his more bewildered patients to read aloud to the nurse as a routine procedure for the purpose of achieving a calm, deliberate, well poised enunciation. Headings from an old newspaper, or the Holy Scriptures were often used as being devoid of exciting qualities. Later such interesting subjects were selected as familiar poems. By and by it was urged that efforts be made at elocutionary art, lending expression, emphasis, pathos, or humor to the articulation, also to practise overtones, rhythm, cadences. Similarly a performing on some familiar musical instrument, as the scales on a piano, well-known tunes and the like. Here brain and hand cooperate. Singing is well known to steady the speech of a stammerer, to readjust the dissociated elements involved in the mechanism of speech defects.

It is also well known how restful and restorative is change of scene upon overwrought nerves. This involves some effort, produces a comfortable weariness, due to the agreeable stimulus of planning, travelling, shifting of the point of view to be substituted promptly by another, the unexpected, a sustaining of interest and attention. Many times when acting as Dr. Weir Mitchell's secretary I wrote at his dictation to physicians to send the patient along and not to wait, to put her or him on a train at once. He assured me he had never known harm to follow, always relief. By the same token I have known him to urge a vastly puzzled and over-anxious husband to take a wife, a mass of neurotic distress, upon a long journey, even to cross the continent, stopping here and there. At first it astonished me to learn how marked an improvement would follow.

The problem of the neurotic, the psychopathic, no matter how much false feelings of weakness, of weariness exist is often to be solved by some form of muscular activities carefully adjusted. It demands as much care and skill to prescribe forms of exertions as to select and administer medication. Here we come to the realm of "occupation therapy," a large and important theme.*

The factors here are the imperative needs for motor discharges as agencies for tranquilization. The conditions to be relieved are strained attention, psychic hypertension, often of tonic protective spasm, prodigalities of inhibition and the confusions, the bewilderments of self-imposed, often unconscious restraints.

*Dr. W. A. J. Maloney has elaborated in a masterly fashion systematic movements, first passive then active, to restore confidence in the ataxia of tabes.

What these restorative activities should best be, how to choose them, and what kind of guidance during their performance it is the function of the physician to supply and to carefully and consistently supervise. To omit such supervision, and for a long enough continuity is to court disaster or defeat. The important topic to discuss here is the primary forms of muscle reeducation which most readily and assuredly will supply the element of tranquillity.

Principles of Movement to Govern in Training Muscles to Achieve Tranquillity, Automatic Poise, Economies of Functioning. — These will be sketched out briefly and graphically to represent them in a citation of those movements made by an expert violinist, which, so far as my observation goes, seem to typify the perfection of motor adaptations to the highest productions. Other grouped movements equally exact, skillful, and poised could be used. The performances of a violinist are much more commonly observed, can be studied by anyone who feels enough interest in the subject to make his own selection.

And first let me here repeat the law of economic motor energizing I have formulated which can and should be followed by anyone who is ambitious to get the highest productivity from voluntary motions:

Begin every movement from a condition of perfect relaxation (zero), increase the power gradually to the point of fullest tension (maximum), and then hold this tension for an appreciable time.

This law obtains for extension, flexion, torsion, or any modification or combination, as to velocity and direction, or semi-voluntary (as of the abdominal walls, the thorax and the like). By observing this rule there is achieved not only fullest manifestation of power, of function, in the moving structures, but also when completed the fullest reaction or resting phase.

Note that should there be any contracture or hypertension whatsoever in the group involved, this tension will militate against the perfection of the willed movement; the tension must be relaxed before the movement can be accurately performed.

Should there exist any subtension, the muscles are thereby thrown out of their alignment, the energy expended is side-tracked to some degree, not only wasted but applied uselessly to those performances which can be merely a hindrance to full motor functioning as is then willed.

As illustration of a perfect extension act involving the entire body directed undividedly to reach out the whole concentrated will power upon the neuromuscular mechanisms at one point, let us visualize a fencer's thrust. Here the fencer is first poised to the best advantage attainable upon his hips, legs and feet, his body is resting easily on this base, his arm is in the position to not only thrust but guard, his hand holds the foil with every finger adjusted to not only retain the weapon but to meet any counterthrust of his adversary, and his objective is to strike at a point (which has position without magnitude) aimed at, and so soon as that point is touched to immediately recover, get back to his original attitude and in perfect poise to meet any attack in kind.

The contest may become prolonged, hence his only hope to retain energies which shall outlast those of his opponent is by not squandering one bit uselessly. Hence he must so adjust his acts, his expenditure of force, as to achieve his uttermost and to secure all the rest possible. This can only be done by observing perfect relaxation when possible, and at least to waste no force.

In accord with these principles in achieving purposive control, an over-tense patient should be urged to issue his own specific commands to each part, limb and semi-voluntary muscles, those of the chest, respiratory, the abdominal walls and even to the intestinal walls which can be thus made amenable to domination.

The local evidences of hypertension are pointed out to him, the kinds and degrees of volitional control which when demonstrated often cause surprise. Later these over-tensions are shown to have disappeared—at least for the moment—but he should be warned that they will occasionally return to vex, until by sufficient repetitions they disappear entirely.

Control will become first habitual and later automatic. Until this complete self-mastery is achieved the relaxing ritual should be practised not only as a routine measure but as occasions arise, during states of aggravated suspense, confusion, anxiety, or loss of emotional balance.

The seance can be done at any time or place without attracting attention, in company, under the eyes of the public, in a conveyance, or while kept waiting for some person or event. Of course best effects follow private practisings; a good time is when resting at ease, composed for a nap.

This ceremony serves as an extraordinary means of energy renewal, especially as a preparation for facing some unwonted or difficult or dreaded situation, interview, or duty.

Ceremonial for Inducing Relaxation.—The series of procedures outlined below is the product of much reading and experience, and has been used by me for many years in its present form, subject to such modifications as may seem desirable in the instance. The patient can use this, and is encouraged to do so, more or less frequently, especially on going to bed, since by it sleep is greatly expedited. It does not induce sleep but merely a state which Boris Sidis calls "hypnoidal," one of mental distraction, in which the subject is peculiarly susceptible to suggestion by the physician or by the patient himself, for whatsoever purpose is desirable. The primary object is to achieve complete relaxation. It is especially helpful in securing a state of receptivity for self-suggestions.

I begin by explaining the objectives simply yet fully. The individual is taught to acquire full self-mastery of the entire organism, in so far as parts are subject to volition, to learn how to take charge of all acts so that the whole shall dominate each and every part and how to prevent a disordered part dominating the consciousness. In the process each limb receives specific directions what it can do, and what it should not do, using as much positive suggestion as possible, with only such negative suggestions as are

obviouly needed. Negations are as a rule unnecessary and undesirable, hence should be omitted. The total body and mind is to be freed from subconscious domination and thus to achieve conscious control.

As to details it is better that the patient should lie down, limbs outstretched, on a couch or in an easy chair. The explanations are set forth and the patient is directed to breathe consciously and a little more deeply or fully and slowly than is customary, and is told that this is for the sole purpose of directing attention to respiration as a means of distracting attention from outside happenings capable of diverting the mind and of fixing it upon the problem in hand.

I usually direct five deep breaths to be taken, and then to suggest the coercion of the right arm. This can of course be thrust out, or pulled in, or twisted, etc. All such would be waste effort, hence it is better that none of these things be now done, but direct that the push shall balance the pull by which a masterly inaction or passivity is attained. Then five deep breaths are taken and the left arm is addressed in the same fashion; five more breaths then the right leg, five breaths and the left leg, five breaths and the abdominal muscles, also the intestines. Now the nature of peristalsis is explained, so of noises in the intestines, due to irregularities in the contractions which should be coerced into regular rhythms, etc., etc. Finally five breaths and the neck is considered; most nervous persons and many who "have no idea they have any nerves" are none the less tense in the neck muscles. This is ample cause for local tension, hence of aches, of weariness, a wish for a pillow to support the neck, etc.

After each limb is thus adjured the physician should demonstrate its flaccidity by lifting it, moving it about, and if any subtension persists it should be pointed out and further suggestions given and testings made until all have disappeared.

The patient should be made to clearly grasp the purpose, which is that he shall learn the accomplishment of voluntary letting go at every point, to reach the zero of movement all over, a state of poise through self-direction, to achieve full command of every muscle in this negative or intemediary phase, to release wholly all tension, conscious or subconscious.

The whole ceremony occupies about ten to twelve minutes. The patient has then "boxed the compass," gone the ambit of restraining familiar movements, has "become captain of his own" mechanisms. While the patient is in this peculiarly receptive state other suggestions will prove especially helpful and lasting—the patient is in command of himself, not of another. His sense of personal responsibility is at its highest; he has done all this of his own volition, hence he can and does the more readily understand, appreciate, and make his own any counsel he may accept, any encouragement or explanation offered.

Furthermore, my long experience in the use of this form of mental and physical distraction leads me to believe that this state of complete tranquility forms the most favorable ground for repair of any or all body cells as well as of mental or emotional disorders.

It is my firm belief that this reeducative procedure should prove a boon to clinicians in affording a position of advantage, as a preparation of the body protoplasm to respond most favorably to any remedial measure.

1504 Pine Street.

THE ROLE OF THE NEURONES.

By J. HENRY DOWD, M.D.,

BUFFALO, N. Y.

In speaking of neurasthenia, a purely functional condition arising in the brain cells, Prof. Shaw, in his treatise on nervous diseases, says, "This inherited unstable state of the nervous system depends evidently upon some defect in the power of the neurones to assimilate and store up nutrition and force in sufficient quantities and with sufficient rapidity to carry on fully and easily the work of life."

Drawing somewhat one one's imagination, the neurones can be compared to the storage cells of a battery; they can be charged, thereby retaining their energy for future use.

We fully realize, and accept as proved that hemoglobin is necessary for the life of the red cells, protein for muscles, and calcium for bone; they are the foods of these tissues, so to speak.

From the statement of Prof. Shaw two suggestions loom forth very clearly: (1) The nerve cells must have a food; (2) this nourishment or food is not only absorbed in sufficient quantities to carry on the daily calls for energy, but an excess accumulates in the cells as a reserve for future use, for times of emergency when sufficient food is not taken by mouth to supply the demand, yet functions must be maintained. That such a condition is a wise provision of nature must be clear; it is simply a method of preparedness on the part of the human system.

We fully realize that the brain controls every action, thought, word, or deed of the human being. It also furnishes power for all functions asleep, awake, sick, or well; when the human being is deprived of nerve power, life ceases at once.

As with all other nutritions, the food of the nerve cells is taken from the food we eat, being converted by a process of metabolism into phosphorus compounds, lecithin and nuclein; this may be called the afferent process. Following this, when the aforementioned have performed their functions, we have the throwing off of the waste, or efferent process—the destructive metabolism. These substances appear in the urine in part as phosphates. This process can be well termed metabolism, it bears the same relation to the nervous system that the formation of urea does to the muscular system.

Phosphoric acid occurs in the urine in combination with the alkaline earths as earthly phosphates, in the form of calcium and magnesium, insoluble in water but decomposed by certain acids and soluble salts. Earthy phosphates are found in freshly passed urine, giving it a greenish hue, or they may appear on boiling; both are quickly dissolved by the addition of acid. Under the microscope the earthy

phosphates appear as microscopical sawdust, if this term may be used. It is this variety of phosphates that is found in diseases of bone, as rickets, ostitis, and the like; also following a meal rich in vegetables, which may render the urine alkaline temporarily.

This variety of phosphatic elimination may be dropped from further consideration. When these phosphates occur in the urine in any quantity they must be removed by filtration before the estimation of the alkaline phosphates about to be described.

The alkaline phosphates, which become evident to the naked eye only on precipitation with the ammonio-magnesium mixture, occur as acid sodium and potassium phosphate. These are seen as crystals, fern-like in character, but they vary greatly as to size, shape, and the appearance of their feathery sides.*

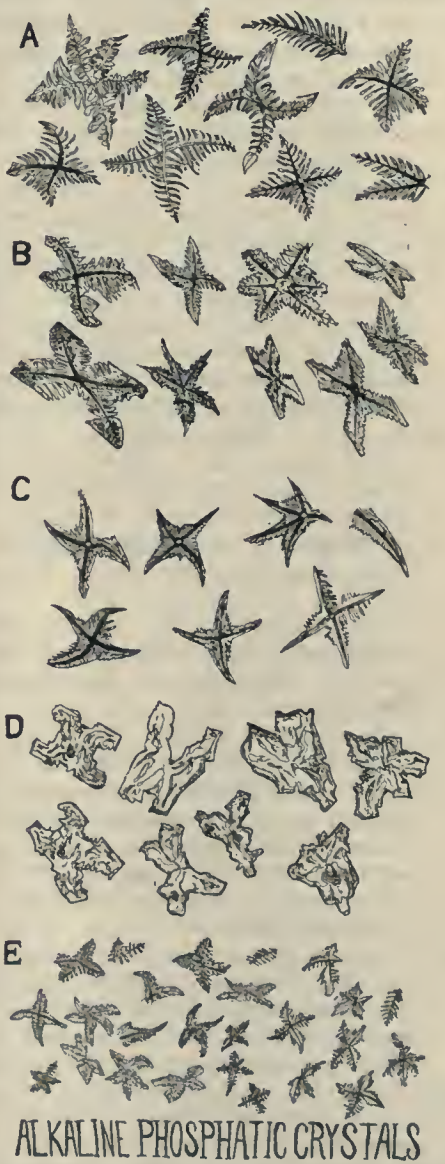
The alkaline phosphates are increased accompanying certain diseases of the lungs, as pulmonary tuberculosis, but mainly in conditions involving the nervous system. Thus, in supersensibility, or excitability of the nerve cells, they are found greatly increased. Let this irritability continue for any length of time, with its increased output of phosphates, and we sooner or later find them greatly decreased, far below normal; the reserve is becoming depleted. Accompanying this condition we will have related systemic manifestations develop, commonly known as neurasthenia.

Normally about 2.5 grams of phosphates are excreted daily. They increase after the mid-day meal until evening, when they fall again until the following day. This phenomenon is easily explained. During sleep the brain is practically at rest, even those functions that are absolutely necessary, namely, breathing, circulation, and elimination are at a low ebb, little or no energy is being called for; it is at this time the neurones are recharging the brain cells in anticipation of coming activity. From mid-forenoon until evening the brain cells are called on for their greatest activity; nerve metabolism is at its highest point, also the elimination of the alkaline phosphates.

This is under normal conditions, but let anything occur that will increase nervous excitement and the elimination will increase in proportion. This increase will take place, even though no food is taken; it is the reserve that is furnishing the excess. Let such a condition continue for any length of time and it will be found the alkaline precipitate is decreasing; registers minus on the phosphatometer; the cause is quite clear: the reserve is becoming depleted. At the same time other changes will be observed, the crystals will change in character (see the illustration).

A definite analogy can scarcely be made between the alkaline crystals and the red cells, because, in the latter case we can see the cell distinctly, whereas, with the former we see but a reflection of the neuronic action. Still, on the other hand, a fairly accurate comparison can be made as far as the crystals go as an aid in diagnosis; clinically they will be found as valuable as blood cells, if not more so.

In the case of a minus phosphatic index, where the crystals may be greatly decreased in number, it cannot be said that destruction of the neurones has taken place, but it may be assumed, with a reasonable amount of sureness, that the neurones are all not functionating normally.



ALKALINE PHOSPHATIC CRYSTALS

(On several occasions I have observed a total absence of alkaline phosphates for several hours. These cases usually occurred in hysterical individuals; valerian brought about elimination.)

*In at least 30,000 examinations of the urine made by the writer, these crystals have never been observed, except after precipitation with the solution mentioned. This statement has been substantiated by Dr. Dewitz, assistant to Dr. Chas. G. Stockton, in 25,000 examinations.

The appearances of the crystals under the microscope can be favorably compared with blood cells, as we view those for hemoglobin; in size, shape, and density they show the amount of nutrition in reserve, how it is being used, and any changes that the nerve cells may be undergoing. Briefly the action of the neurones may be summed up as follows:

A. 1. Normal crystals. Note the almost similar and well-formed feathery sides, resembling the fronds of a fern, also the density of the crystals.

With the phosphatometer registering N. P., using the blood by way of analogy, we would find a normal red cell count with normal hemoglobin. Finding such a condition, no matter what the symptoms may be or the condition present, the nerve cells as a factor in the case may be eliminated.

2. Normal crystals, plus index (solid above N. P.) irritability or supersensibility of the neurones. Sedatives are indicated.

3. Normal crystals, minus index. Neurones are not all functionating. Making a blood comparison, red cells would be found deficient, but hemoglobin normal.

B. Crystals light in weight. In this connection the precipitate will sink very slowly, or not at all (allow but ten minutes). As to the amount registered on the phosphatometer neuroinidia is present. Note the different shape of crystals; the feathery sides which are sawtooth-like in appearance, also the lack of density as compared with the normal. Where this condition is found, no matter what may be the case under consideration, very feeble efforts toward resolution will be forthcoming until nerve-cell nutrition is supplied. Such a condition is practically always present in pain of an indefinite nature, neurasthenia, neuritis, and the like.

C. Disappearance of the feathery sides; this shows pregnancy between the third week and the third month of uterogestation (Year Book, 1906).

D. Amorphous crystals. When the use of alcohol, tobacco, or drugs, as morphine, cocaine, and the like, in excess can be eliminated, a fairly constant appearance of these crystals shows an oncoming nerve-cell degeneration. Crystals of the amorphous variety may be found with a plus or minus index.

E. Normal shape, but very small. These crystals show nerve cell irritation, and are commonly found during or preceding hysterical attacks. The index may be either plus or minus, generally the former.

Ascertaining the phosphatic index, with its resulting formation of the alkaline crystals is a very simple procedure. As with blood cells, casts, and like objects viewed by the microscope, a little care must be used at first before drawing definite conclusions.

Using the second urine passed in the morning (see MEDICAL RECORD, May 2, 1908) fill the phosphatometer to U, add solution (magnesium sulphate, chloride of ammonia, aqua ammoniæ (10 per cent.) of each one ounce, water 8 ounces D to S, shake thoroughly and set aside for ten minutes. The solution should turn milky at once, and in a few minutes commence to settle. The phosphatometer being graduated as to normal precipitate, plus or minus, in ten minutes the amount of alkaline phosphates present will be clearly indicated. The crystals will have a definite and constant appearance at the end of ten minutes, and although they will not change in character, no matter how long they stand, the index showing nerve metabolism must be read at the end of ten minutes.

Briefly reported, the following cases will show the great value of alkaline crystals as an aid in differential diagnosis:

CASE I.—Severe neuritis left brachial plexus; medication gave no relief. Index taken showed N. P. crystals A. Suggested that condition was due to pressure. A surgeon found this to be the case; removing the same gave instant relief.

CASE II.—Brachial neuritis of some eight or nine weeks' standing. Aspirin, bromides, valerian, electricity, and the like gave no relief. Index taken showed 90 per cent. minus, crystals B. Mist. phos. comp. (Dowd), 30 minims, in milk three times daily half an hour after meals, gave relief inside of three days. Three weeks after, index registered 10 per cent. minus, crystals A; there was no return of the condition.

CASE III.—Miss S., no menses for two months. Examination did not show anemia to be present; no pathological condition, but an index 100 per cent. plus (evidently due to the great mental strain she was under), crystals C. At first she denied sexual relations, at least coitus. When apprised of her condition she admitted that seminal fluid had been deposited against the vulva by her fiancé; she was married at once; a child arrived seven months later.

CASE IV.—D. L., January 21, 1919, consulted me for a nervous condition; pronounced neurasthenia at the time. Index 70 per cent. minus, crystals D. His family was apprised of the suspected condition that seemed evident. On November 11, 1919, he was committed to the State Hospital as insane.

CASE V.—Mrs. T., in bed three weeks, claimed she could not stand up and was becoming blind. Good appetite, slept well; the family physician had made no diagnosis. Before seeing her in consultation I requested the urine for examination. No pathological condition was evident, index 15 per cent. minus, crystals E. Valerian and the bromides gave no result in ten days or so. I advised the family to give her no food unless she came to the table for it. She appeared for breakfast the second morning; has had no further trouble. Diagnosis, hysteria.

9 NORTH PEARL STREET.

HYPERCHLORHYDRIA—A FREQUENT CAUSE OF DEFECTIVE APPETITE IN CHILDREN.

BY JAMES HOYT KERLEY, M.D.,

NEW YORK.

AMONG the cases which the pediatrist and general practitioner are called upon to treat no one occurs with greater frequency or claims more attention than that relating to the appetite and diet of the child. This is especially true of older children, for infants may be managed by lengthening the intervals between the nursings or bottles, by shortening the nursing period, or, if on the bottle, by cutting down the fat or sugar content of the milk formula.

The type of patient we are about to consider is the older child, whose appetite is poor in consequence of a condition of hyperchlorhydria or hyperacidity with its accompany-

ing symptoms. The history most frequently obtained here is that in the feeding intervals the desire for food is very marked, in fact at times almost voracious, the child being unable to wait until mealtime. He starts the meal very well, but after taking a small quantity of food his appetite is quickly satisfied, and he turns away thoroughly appeased. This is repeated time and again, with the same intense initial desire, and the same rapid appeasement.

After eating there is complaint of a feeling of fulness in the epigastric region, often accompanied by indefinite pains in the region of the umbilicus, which may radiate to the right inguinal region, simulating a chronic appendicial pain. Accompanying or shortly following this sensation of discomfort are acid eructations of gas, with the resulting heartburn, and burning in the stomach.

The duration of the acute symptoms is variable, disappearing usually in the course of an hour. The breath of these children is usually offensive and the tongue coated. Constipation is the rule. In appearance they are apt to be anemic looking, with sallow complexions. They are moderately underheight and underweight, tiring easily on exertion, and they do not have the ability to withstand physical stress. Examination of the gastric juice reveals an increase of both free hydrochloric acid and total acidity.

The prognosis is very favorable for the relief of the immediate symptoms, and if the proper dietetic and hygienic measures are instituted and followed no subsequent trouble is to be anticipated.

The dietetic history usually obtained from the parents in these cases is that the juice of one or two oranges has been given the first thing in the morning, followed by a breakfast of one or more eggs daily. For the midday meal a highly seasoned soup has been given, or red meat, such as steak or roast beef, has been eaten daily or every other day. In like manner ice-cream has formed a favorite dessert. Oftentimes tea or coffee has constituted an important part of the diet. Between meals candy has been eaten *ad libitum* and ice-cream sodas indulged in frequently.

In the treatment alkalies are given to neutralize the excessive acidity. A prescription such as the following, given in water fifteen minutes before each meal, has been found very effective:

℞ Magnesium carbonate, gr. xxx
Sodium bicarbonate, ʒi
Bismuth subcarbonate, ʒi
M. Ft. Chart No. XXX.

For the constipation a rhubarb and soda mixture combined with aromatic extract of cascara, in one to two dram doses at bedtime, is indicated.

The diet plays a very important part in the prevention and cure of this condition. The mother is to be instructed to see that the child has nothing very hot or cold, very sweet or sour. Everything eaten is to be thoroughly masticated, and the patient must be made to spend the proper amount of time with his food and to avoid any semblance of rush or hurry. Orange juice, if given at all, is to be allowed only with or after the morning meal; never before. At the beginning of treatment it would be well to discontinue it entirely and to substitute prune juice. The albuminous part of the egg only is to be eaten, as the yolk tends to strongly excite acid secretion. Highly seasoned soups should be interdicted and red meat served only once a week. All excessive sugar, also candy, sodas, ice-cream and pastry, are to be avoided. Tea, coffee, and ice-water are harmful. Raw fruit is not permitted until the appetite has become perfectly normal. A diet of farinaceous foods with milk, potatoes, green vegetables, meats (except red meat), stewed fruit, and wheat bread, toast or zwieback, is to be followed. The milk should be limited to one pint a day, with the water taken mainly between meals.

Due attention must be paid to the proper hygienic measures in the treatment of these patients. The right amount of rest is to be insisted upon, especially when the child has been under some mental or physical stress. An entire change of scene is advisable, if possible, for the worst cases, these doing well at either mountains or seashore. For the others, late rising, an afternoon rest period, and a cold sponge bath followed by a brisk rub at night, after a day of healthful out-of-door physical exercise, are valuable aids in the treatment.

Conclusions.—A common cause of defective appetite in children of the runabout age, or older, is hyperchlorhydria, with the resulting symptoms of variable desire for food, indefinite abdominal pains, flatulency, and acid eructations.

In the etiological relationship dietary indiscretions play an important part.

The treatment consists of giving alkalies to neutralize the excess of acids, of substituting an easily digestible, non-irritative diet, and of giving due attention to general hygienic measures.

65 East Ninetieth Street.

THE PHILOSOPHY OF HUMAN SYMPATHY.

By J. C. Bateson, M.D.,
Scranton, Pa.

The term sympathy is derived from the Greek, signifying to suffer with, and has a variety in its phases of meaning according to its various uses; physiologically, it may be an influence produced in any organ by disease or disorder in another part. Or it may be a relation which exists between the mind and the body, causing the one to be affected by the other. It also may be the influence exerted by one individual upon another, or received by one from another.

As examples, we may have pain in the forehead by taking ice cream or ice water into the stomach, or pain in the right shoulder from disease of the liver, or irritation and nausea caused by a tumor of the brain. The close relationship between the phrenic and pneumogastric nerves and the sympathetic nerves, explains the reason why there may be produced a case of hiccough or nausea when the stomach is free from trouble in itself.

A certain specialist rightly declares that the sympathetic nerve system has a mind of its own, and therefore not dependent always on the cerebrospinal system. This perhaps explains why at times the influence afforded by the sympathetic, may

serve to effect a cure independent of the cerebro-spinal.

Mind and matter are both God-given, and inseparable in human life, and the relationship existing between them is of a most delicate and occult nature. Therefore, we may define sympathy, physiologically, as a relation which exists between the mind and the body, causing the one to be affected by the other.

This accounts for the correspondence of various parts or organs of the body in similar sensations, symptoms, or affections of the whole body or some part of it, in consequence of an injury or disease of another or different part, or of a local affection.

Again, sympathy is the influence exerted by one individual upon another, or received by one from another, and the effects thus produced are seen, as for instance, in yawning and more potentially in hypnotism, and in the transfer of hysterical symptoms, which particularly and frequently affect young women.

Yawning, or pandiculation, is a sympathetic habit, produced by a deep involuntary inspiration with the open mouth, and often accompanied by the act of stretching one's self. This is liable to occur when one is confined in a close room where the oxygen of the air is deficient.

The word hysteria is mainly applied to a condition in young women who lack control over their conduct and emotions, through exaggeration of sensory impressions and simulation of various disorders. The principal cause for the prevalence of this nervous disturbance is, in most instances, defective physical and mental training.

It has been noted by experienced observers, that many lives were lost during the recent widespread epidemic of influenza (1918), because of a sympathetic fear and apprehension. This form of sympathy is better known as pity or compassion—the feeling or suffering of one person, excited by the distresses of another, and which, when not kept under control, is liable to result in serious consequences.

According to the late Dr. James McCosh, former President of Princeton University, we put ourselves in the position of others, by calling up the same feelings which go out in the same manifestations. The sight of tears is apt to call forth tears in the beholder, or quite as readily in the listener to the story told which makes us realize the position. It is the same with laughter, which is apt to be echoed back till the noise rings throughout a large assembly. And when an entire company is moved, it is difficult for any member of that company to keep his composure. An alarm of fire will spread through a vast congregation, and many become panic-stricken when they are actually cognizant of no cause of fear.

There is in some measure a reflection of emotion from every person upon every other person, within his or her radius of observation. We call this a kind of contagion; it is, however, a contagion produced by an unconscious influence upon others to cherish the same feelings, and thereby produce the same outward manifestations as are controlling the feelings of the active personality. In like manner, the contagion of disease is made more powerful when persons are afraid of it, and when they dwell and brood much on the threatening infection.

History records sympathetic epidemics, such as the dancing mania which spread over many countries in the Middle Ages. This delusion took on the form of a wild dance, known as that of St. Johns or St. Vitus, after the effects of the "Black Death" had subsided in central Europe. Other examples are furnished by the dervishes of the East, and the "Jumpers" in misguided religious revivals in the West. These affections seem to be produced by persons entering into sympathy with those who manifest that state of feeling.

In genuine feeling, sympathy is rooted and grounded in love, and is a branch of love, and a grace of high order. Love begets sympathy. Even the innate selfish soul may be so ennobled by a true passion, as to find in its own transports the desire to share the joys of a completed life, and in true humility of gratitude, seek to lessen the burdens of the over-burdened.

We are commanded to "rejoice with them that do rejoice and weep with them that weep." In this manifestation, our hearts are responsive to the hearts of others influenced by their emotions. We enter into their feelings; we identify ourselves with them. So when we see others laugh, we are apt to laugh also. We weep with those that weep, if we share their sorrow. Opposed to this is hardness of heart, which is insensible to the wail of misery.

Sympathy governed by a liberal mind knows real generosity, and is capable of reaching the heights of self-sacrifice. It is a mutual feeling, reciprocal to give and receive mutually. While love means a devoted affection or attachment, including sympathy, the latter does not necessarily include love.

Mercy is used in the sense of leniency, but sympathy includes all this with justice and fellow feeling added. And yet it is true, as set forth by a noted writer, that many a poor wife has swallowed her dinner without tasting it, because her inconsiderate husband chose this inopportune time to find fault with her, the children, the servants, and with everything except himself. The beef is too tough, the vegetables underdone, and the soup is cold. He frets and scolds to the great disturbance both of his own and his wife's digestion. Such examples rightly belong to the heathen philosophy which discards all sympathy for those who suffer, because such condition is to be thought of as not being real.

As was reiterated by John B. Gough, there are men who wear smiles on their faces, whose hearts are unprincipled and treacherous; but there are true men with a rough outside, who speak with their hands more than with tongues, with deeds rather than words. There are brutal hard men; but there are many loving friends, who act as a balm to the rankling wounds of humanity.

And this is true with most men in the medical profession. While there are men full of gall and bitterness, hateful and hating one another, and physicians who relieve suffering simply for a livelihood, there are also noble and compassionate spirits, whose "charity thinketh no evil, suffereth long, and is kind."

In the language of Emerson, we have the heroic who cannot be the common, nor the common the heroic. We have a right to expect the sympathy of those people whose actions excel only in that they outrun sympathy by appealing to justice.

But sympathy implies kinship with all the world. It is the yeast that leavens the bread of life, and bulwarks the Adam weakness of finite souls to brave and to endure. Then, if we would serve our brother, because it is fit for us to serve him, we must not take back our words when we find that prudent people do not commend us. We must be true to our own acts, and console ourselves, if we have done strange and extravagant things and broken the monotony of a decorous and conventional age.

One mission of pain, undoubtedly, is to move hearts, says Hugh Black, that otherwise would be hard and selfish, to the noble fellowship of consolation. We have learned that compassion and sympathy will unite men whom no argument would or could bring together; and these sweet graces are called forth by this very suffering which is a phase of this subject and a part of the problem under consideration.

Notwithstanding that so-called Christian Science teaches that "there is no truth in pain and no pain in truth," we know what it is to be compassed about with infirmity, to have compassion on our fellows who suffer and who endure pain, and thus bear gently with them. To such the recognition of nature's bond comes in a flash, a gleam of intuition. It brings sympathy, and sympathy unites men as no written bond can, though it were attested and secured by every legal means.

Similarity of experience will beget sympathy. So that it is not strange that: "He jests at scars who never felt a wound," or that a person who has never had a pain, may try to think that there is no pain. It is natural to become self-centered, and heedless of others. Sir Walter Scott, who had eyes for the great common facts of life, makes Jeanie Deans say in her sore trouble, "Alack! It is not when we sleep soft, and wake merrily, that we think on other people's sufferings, but when the hour of trouble comes."

If we had not known something of pain, our hearts would have been harder and less compassionate and loving than they are. We can feel the force of the beautiful appeal found in Deuteronomy, "Love ye therefore the stranger, for ye were strangers in the land of Egypt," we know the bitterness and the anguish and the loneliness of it. The "Great Physician" gave a striking illustration of human sympathy, in the parable of the "Good Samaritan." So did our Christian organizations and Red Cross workers show a wonderful manifestation of sympathy in the recent world war against autocracy and barbarism.

It was sympathy expressed in love with sacrifice, and a demand for freedom that caused our forebears to starve and freeze at Valley Forge. It was sympathy with an outraged and terror stricken nation that left heroes of the far flung battle line who fought on Flanders field.

This is proof positive, that it is futile work to try to catch grief with proverbs, to "charm aches with air, and agony with empty words." And yet this is believed in by many good people of civilized as well as heathen countries. With them it is thought that pity is akin to contempt. But there is a saying far truer, that pity is akin to love, and without that there is no real and lasting charm in human life.

Compassion is the crown of virtues, because without it we would all degenerate into a more or less selfish condition, for faith without works is dead. Therefore, sympathy can be accepted as an almost universal solvent. Nothing of a noble character is understood without it. The whole civilized world is reaching out a hand of sympathy to the starving and oppressed in war and famine devastated lands; more extended action is being taken and movements are under way to bring about greater and better privileges to greater and larger numbers, for the pursuit of life and happiness. This strongly indicates that there is more sympathy manifested in the world to-day than ever before.

It is sympathy whose "star dust" vision broadens horizons, till all personal or individual gain is merged in the purpose of a worldwide welfare. Whose scope is limitless, and whose possessors care only for a perfect fruition; that compensates for any or all loss to self, in making supreme sacrifice.

Sympathy should not be confused with kindness, a state or quality of being kind or humane; for such manifestation may be performed in a sense of duty rather than through real sympthy.

The very depth of sympathy that is in some people makes them appear unsympathetic. "The heart knoweth its own bitterness and a stranger meddleth not therewith," so that many people shrink from meddling with sorrow. Someone has pointed out that if you wish to do good to a certain class of people, you must get under their skins; they will then feel your sympathy. With the sorrowful and needy is found the "open way" to Heaven's gate.

An invalid will sometimes remark to the attending physician: "I always feel better when you come," and he is better, for "the tongue of the wise is health." The true doctor or nurse should have this soul ingredient in its extreme sense. To say that such professions find more successful exponents in the ones without sympathy and its weakening reactions, is as erroneous as to applaud a lack of tenderness in one whose influence is of moment to a general public.

It was sympathy with poverty and suffering that established free clinics, free hospitals, and prepared the way for missionary service in foreign lands. It is through suffering that we learn how to sympathize. Therefore, it is not becoming to keep our alabaster boxes sealed until our friends are dead. Nor is it very helpful to offer conventional consolations, conventional verses out of the Bible, and conventional prayers to those who are torn with intolerable suffering. To Job's comforters, Job's question is suitable, "How long will ye vex my soul and break me in pieces with words?"

Sympathy is the active principle of the soul; it makes for the stability of man's fellowship with man; it is the foundation of the Christian religion; and in its simple God-given fullness, equips those who recognize its possession, for all the capacities of a complete and beautiful life.

COMPULSION NEUROSES (OBSESSIONS, DOUBTS AND PHOBIAS).

By H. LAVESON, M.D.,

NEW YORK.

Compulsion neuroses is one of the most important problems with which abnormal psychology has to deal. The phenomena are psychological and physical. They occur in sporadic form. They may be arranged by gradations in types in which they appear:

A. As purely physical disturbances (tremors).

B. As physical disturbances plus conscious emotion (anxiety neurosis).

C. As physical disturbances plus conscious emotion plus a specific idea of the object of the emotion but without logical meaning (phobias).

D. As physical disturbances plus emotion plus idea plus meaning (unreality syndrome).

The Psychogenesis of the Compulsion Neurosis.—In the first type the physical phenomena can be traced to a functioning subconscious emotional complex of which the phenomena are physical manifestations; in the second to a functioning subconscious complex ejecting its emotion into consciousness; in the third we find by analysis an associated unconscious complex setting which logically would account for the emotion of the obsessing idea, and we infer, by analogy with the first and second type, that it is a dynamic factor in the psychosis; in the fourth we find a similar complex which logically would account for all the physical and conscious phenomena.

Type A. The subject manifests marked tremors in the hands to such an extent that the cup in her hand shakes and rattles in its saucer. She complains that these tremors are annoying her, especially in the presence of another person. At times she gets awfully hot all over and breaks out into perspiration. She has for a long time been absessed with the insistent foolish idea that if people knew she manifested these phenomena they would not care to know her socially. It was a point of view which had been more or less obstinately maintained in spite of all contradictory arguments. The idea had specifically recurred from time to time in particular situations, and had caused considerable emotional disturbance.

Complexes consisting entirely of the physiological manifestations of emotion without conscious emotion undoubtedly occur. The symptom complex may be interpreted as a persisting automatism derived from antecedent fear states that had been outgrown. From our present standpoint and fuller knowledge we must believe that underlying this automatism is probably an unconscious complex of these antecedent experiences, including the fear which takes part in the functioning mechanism. It may then be called a subconscious psychosis.

True hysterical laughter and crying are undoubtedly phenomena of this type and due to the same mechanism. These phenomena are well known to be purely automatic, that is to say, they are emotional manifestations unaccompanied in consciousness by thoughts or even by emotions corresponding to them. The subject laughs and cries without knowing why and without even feeling merry or sad.

Type B. In this class the subject is afflicted with attacks of conscious emotion, most conspicuously and commonly fear, plus the same physical disturbances as in Type A, but without any specific idea in consciousness to which the emotion is related.

A typically perfect example of anxiety neurosis was shown in a patient with recurring attacks of intense anxiety accompanied by a feeling of suffocation and oppression of the chest. Investigation disclosed that the first attack immediately followed a dream which was forgotten but recovered in hypnosis. It appeared that in the dream she was accused by a certain person of certain delinquencies (self-reproach) and threatened with exposure. At this point in the dream she was overcome with fear and anguish as in the after-attacks. It also appeared that previously she had been and still was apprehensive of this person's loyalty. By inference and analogy with the well-established after-phenomena of dreams we must assume that the dream process still functioned subconsciously and produced the anxiety attacks.

This type will be discussed more fully below in a section following the general review of the compulsion neuroses.

Type C. In this type the affect is linked with an idea as its object in consciousness, but without meaning, so that whenever this idea is awakened it is accompanied by the affect alone. Some of the phobias are the most common pathological examples. Nor is there anything in the content of consciousness which gives meaning to the idea as something that should occasion anxiety. The subject, in other words, does not know why he is afraid of the given object. In such cases the restoration of dormant memories will disclose antecedent experiences in which the idea is set and which explains the origin and meaning of the fear. A typically perfect example of phobia is the following case::

B. C. A., who suffers from an intense fear or phobia of cats, particularly white cats, can recall no experience in her life which could have given rise to it. An attempt was made to recover a possible memory in hypnosis. As is well known, the memory often broadens in hypnosis and events which are forgotten when "awake" may be recovered.

"I think I know about the cats. I can remember myself a little child playing on the floor with a kitten, and it began to run about the room and had a fit, I think, and it jumped on me, and I was alone, and I screamed and cried and called my mother, but no one came, and I was very much frightened. I do not believe I ever told anyone. It was a white kitten. It ran out of the room, and after a bit I went on playing."

Although the conserved experience could not be awakened into memory by voluntary processes of the personal consciousness it could be so awakened by an artificial stimulus under artificial conditions.

In this connection I may instance another case:

C. D. suffers from a fixed fear of fainting. She cannot recall, even after two prolonged searching examinations, the first occasion when this fear developed, or why she has it, and is, therefore, ignorant of its genesis. Yet put into light hypnosis she recalls vividly its first occurrence as the effect of an emotional scene of twenty years ago. The details of its psychological content come clearly into consciousness and its meaning, as a fear of death, is remembered as a part of the original episode. That the fixed idea is a recurrence or partial memory of the original complex becomes logically plain and is recognized as such.

Type D. In this type the conscious psychosis consists of idea, meaning, affect, and physical disturbance.

An example of "unreality syndrome" is the following case:

F. E. suffered from attacks of so-called "unreality"

with intense fear. She was unable to give an intelligent explanation as to why she was afraid of the attacks—harmless in themselves—until it was brought out that there was in the background of her mind the thought that the attacks spelled insanity or that she was likely to go insane, and also death. Following the attacks there was amnesia for these thoughts. Her fear really, then, was of insanity and death. The content of consciousness in the attacks contained the perception of herself as an insane person, thoughts which expressed the meaning of her attacks, and fear. No amount of explanation of the harmlessness of the unreality syndrome sufficed to change her point of view, *i. e.* its meaning to her. But going further it was discovered that her self-regarding sentiment and her ideas of insanity and death were organized with a large number of fear-inspiring antecedent experiences which explained why she regarded the attacks as dangerous to her mentality and life; and why the biological instinct of fear was incorporated with the self-regarding sentiment. These experiences had long passed out of mind and there was no conscious association between them and her phobia, but they could be recalled as associative memories.

Anxiety Neuroses.—These manifest themselves by various physiological reactions upon the organism. Disturbances of the respiration and vasomotor apparatus induced by sensory stimulation are very common. Modifications of the peripheral circulation, manifested through pallor or turgescence of the skin are also common phenomena. A great number of cases show alterations in the rate and rhythm and force of the heart-beat, also temporary dilatation of the heart. This dilatation in some cases is sufficient to lead to incompetency of the mitral valve and to give rise to murmurs.

The respiratory apparatus is markedly affected, as shown by alteration of the rate and depth of respiration. Increase of sweat, sometimes amounting to an outpour, and alterations in the amount of the various glandular secretions (salivary, gastric, etc.), and rigor are important phenomena. The remarkable researches of Pawlow and his coworkers in Russia on the work of the digestive glands revealed that these functions are influenced in an astonishing degree by psychical factors. In hungry dogs a large quantity of gastric juice, rich in ferment, is poured out when food is swallowed, and even at the sight of food, and it was proved that this outpouring was due to psychical influences. Simply teasing and tempting the animal with food cause secretions, and food associations in the environment may have the same effect.

Most of the viscera are innervated by the sympathetic system, and the visceral manifestations of emotion indicate the dominance of sympathetic impulses. When, for example, a cat becomes frightened, the pupils dilate, the stomach and intestines are inhibited, the heart beats rapidly, the hairs of the back and tail stand erect—all signs of nervous discharge along sympathetic paths.

On the sensory side, nausea, dizziness, headache, pains of different kinds are common accompaniments.

Pallor of the skin, increased perspiration, cardiac palpitation, respiratory disturbances, tremors, muscular weakness, gastric and intestinal disturbances —one or more of these physiological disturbances may be so obtrusive as to be the predominant feature of the syndrome and to mask the psychical element which may then be overlooked. Gastric and intestinal disturbances, for instance, or cardiac distress may be so marked as not to be recognized as simply manifestations of anxiety neurosis, but may be mistaken for true gastric, intestinal, or heart disease.

A person, we will say, has acquired—owing to no matter what psychogenetic factor—a recurrent attack of anxiety. This anxiety or apprehension recurs from time to time when awakened by some thought or stimulus from the environment. At once there is an outburst of physiological, *i.e.* functional disturbances, in the form of an "attack." There may be violent cardiac and respiratory disease, tremor, flushing, perspiration, diarrhea, sensory disturbances, etc., followed by more or less lasting exhaustion. Disease of the heart, or of the stomach, or of the nervous system is frequently diagnosed when the symptoms are simply the product of a complex. Quite commonly, when the symptoms are less related to particular organs, but more conspicuously embrace vasomotor, sensory, digestive disturbances and fatigue, the syndrome is mistaken for so-called neurasthenia.

511 East Eleventh Street.

Medicolegal Notes.

Physician's Deposition as Evidence.—The California Supreme Court holds that the deposition of a physician as to an employee's injuries, for which compensation is being sought under the Workmen's Compensation Act, although hearsay as to the employer and the insurance carrier, who were not parties to the proceeding in which the deposition was taken, is admissible under section 60, subd. a of the act, providing that no award shall be invalidated because of the admission of evidence inadmissible under common law or statutory rules.—Ocean Accident & G. Co. v. Industrial Accident Com. (Cal.) 182 Pac. 35.

Testimony as to Health of Insured Person.—In an action on a life insurance policy, testimony of the widow of the deceased that her husband "was not sick" before the date of the policy, "never had any trouble for five years, as far as she knew, except to get a cold," was held insufficient to raise a jury question in contradiction of the attending physician that he had at a specified time treated the deceased for chronic bronchitis and that he was affected by that disease. The deceased could have had chronic bronchitis without being characterized as "sick," by which his widow apparently meant sick in bed, or at least unable to work.—McAuliffe v. Metropolitan Life Ins. Co. (N. J.) 107 Atl. 258.

Expert Testimony—Hypothetical Questions and Personal Knowledge.—An instruction to the jury in an injury case gave the usual instruction properly given in cases where hypothetical questions have been propounded to expert witnesses, and contained the usual caution to the jury that before they could give effect to the opinions expressed by experts upon hypothetical questions, they must be able to find that the facts upon which the opinions were based appearing in the hypothetical questions were supported by the evidence, and said to the jury: "If the facts are not found to be as stated in the hypothetical question, the answers thereto or the opinion of the witness based upon said question is of no value, and cannot be considered." It was rightly claimed that no hypothetical questions had been propounded in the case. No expert witness was called upon to give an opinion based upon a hypothetical question. All the experts who gave opinions (as to whether the injury would result in permanent pain and disability) based their opinions on matters acquired from a personal examination of the plaintiff. While the part of the instruction objected to might well have been omitted, it was held not prejudicial in this case, as the court followed this charge by instructing that if an expert witness testified as to matters of fact from personal knowledge, his testimony should be considered the same as that of any other witness.—Collinson v. Cutter, Iowa Supreme Court, 170 N. W. 420.

MEDICAL RECORD.

PASSIVE HEPATIC CONGESTION ASSOCIATED WITH HIGH BLOOD-PRESSURE.

FROM what is now known there is no doubt that the cardiac liver is frequent in patients presenting a very high maximum arterial tension. It is made manifest either by a painful hepatic paroxysm or by an increase in the size of the liver, which may be very considerable. The production of this venous congestion of the liver is due to the fact that the maximum tension, although it may have dropped several degrees, remains very high, while the minimum tension remains what it was before or may even increase slightly. If the observer is not warned of the possibility or even the frequency of these accidents in individuals having a high maximum tension, surprise might be forthcoming by the appearance of such symptoms; hence the very likely possibility of a mistaken diagnosis, such as hepatic colic, if the phenomena are of a very painful nature, or hypertrophic cirrhosis without ascites, if the liver is moderately increased in size, while cancer of the liver might be suspected in the massive forms.

If, on the other hand, the possibility of these asystolic accidents is known, the diagnosis should be rather easily made, by consideration of the two following facts: First, when the patient with a painful or painless hepatomegaly shows but a slight difference between the maximum and minimum tension—although the latter may be very high—the presence of a cardiac liver is to be suspected and not cancer, ascitic cirrhosis, or simple hepatic colic. To have a proof of this all that is necessary is to put the patient under treatment for asystoly; if the hepatomegaly disappears or simply diminishes to a very considerable degree, a precise diagnosis will be made and the indications of a proper treatment will be evident. If, on the contrary, the size of the liver does not change it will then be logical to conclude that the hepatomegaly is due to some cause other than passive congestion.

The knowledge of these facts leads to another practical conclusion, namely, that the size of the liver should be studied in all cases of high blood-pressure. When the liver becomes painful, when it increases in size, even when no particular attention has been given to the blood pressure, it will be quite logical to infer that the heart has a tendency to dilate and as a practical conclusion these patients should be advised to follow a diet and the kind of life permitting the heart to rest, while cardiac tonics should be exhibited. Briefly speaking, in cases of high blood-pressure the liver is the place in which to look for the initial symptoms of hyposystole and if this notion is constantly present in the clinician's mind many diagnostic errors will be avoided and a proper treatment given in time to prevent the advent of dangerous cardiac insufficiency which always is a menace in such patients.

NEW METHOD OF MARKING THE SKIN TO SHOW LOCATION OF VARICOSE VEINS AT OPERATION.

WHEN silver nitrate solutions are used to mark the position of varicose veins, the marks are often nearly or quite obliterated when iodine is used to sterilize the field. Besides, many surgeons have had the same unfortunate experience as that reported by Coopernail (*Surgery, Gynecology and Obstetrics*, October, 1919) when silver nitrate marking has been left to the house staff; for, as he says, internes, forgetting that the solution does not blacken the tissue at once, have sometimes used a nitrate of silver pencil, and a nasty burn has resulted. Coopernail has found brilliant green, an aniline dye, in aqueous solution most satisfactory. The course of the veins should be marked out with this the day before operation and the solution should be allowed to dry before the clothing touches it. The stain is not removed by alcohol or ether, and shows beautifully through the iodine. Coopernail credits Captain T. D. Buchanan with the suggestion that this would also be a good agent for marking the scalp in proposed intracranial operations.

We cannot agree with the author when he says that the operation for varicose veins most commonly performed to-day probably is the Mayo stripping operation and resection of veins that cannot be stripped; nor can we unqualifiedly agree with the statement that the Schede operation at the present time has become obsolete. Unquestionably the Mayo operation has a certain following, perhaps a large one; but it is by no means universally used, and it is an operation in which there is a considerable element of unnecessary danger, as is proven by the fact that a number of deaths from embolism have followed this type of operation, and this accident is said to have occurred even at the Mayo Clinic.

Regarding the Schede operation, possibly the original Schede, in which an incision entirely encircled the leg, has become obsolete, for there are almost always certain areas where no dilatation of veins occurs and bridges of normal skin and other tissues superficial to the deep fascia may be left, thus allowing passage of cutaneous nerves and avoiding the production of a complete circular scar;

but there are many cases in which the Schede, modified as suggested above, may be used to advantage, sometimes alone and sometimes in combination with the Trendelenburg, Mayo, Babcock, or some other type of operation above the knee.

THE PLAGUE AT AVIGNON IN 1721.

A MANUSCRIPT has recently come to light which represents the journal of an eye witness (the town almoner) of this visitation. Raymond gives a brief digest of it in *Le Progrès Médical* for April 3, xlviii, 14. During the previous year Marseilles had been ravaged and as the contagion neared Avignon prophylactic measures were taken. All of the gates were closed but three which were vigilantly watched. An alleged "first victim" had choked while eating, but this fact was not known and it was thought that he had been instantly stricken dead by the disease. The truth was soon discovered and everything done to calm the people. Certain articles of import in warehouses were suspected, as cotton from the Levant; and as Marseilles had blamed cotton for its visitation these bales inspired terror. All sea food was kept out of the city and beggars about the walls were chased away. Sewers were covered. The sanitary cordon naturally put an end to all business and the workers were thrown out of employment and congregated in the streets, clamoring for aid. Some were put to work mending the streets and others unable to do this, were given alms. The Jews were not admitted to State aid; as they were allowed only a single occupation, the dealing in cast-off clothing, this had to be proscribed for fear of inviting the contagion. Among the numerous prophylactic measures dogs and cats, believed to spread the infection, were slaughtered after having been taken to an old monastery.

These measures were begun late in 1720 and it is interesting to note that the disease did not actually reach the town until September, 1721. Long before that period the funds had been exhausted and the town valuables had to be pledged to get more. Dr. Manne, Jr., physician to the hospital appointed for plague patients, reported the first case but his colleagues disputed his diagnosis—openly in the interest of averting a panic. There was a counter rumor that cases had been concealed since August. Immunes from plague ridden towns came to serve as nurses in the hope of good financial returns.

When the plague had spared the city for about nine months, probably as a result of the vigorous prophylaxis, once gained a foothold it spread rapidly and by September 30 the temporary infirmary was filled with patients, so that two more were opened—religious institutions. The first attendants died from the contagion so that orderlies became scarce. Each new focus of disease required special quarantine and individual activities often clashed. An old leper asylum, long disused, was opened to receive newborn children. The general hospital of Avignon did not want the plague victims, yet could not refuse aid to doubtful cases. An observation ward was installed for suspects and in the meantime the alleged disinfectants which, it is to be inferred, were selected for their agreeable odor, caught fire and destroyed a valuable library belonging to the Augustine monks.

The plague had lasted a full month when it was thought that conditions were on the mend. Renewed efforts were made to speed the day and on the next February a final quarantine preparatory to a clean bill of health was begun. Every doctor who had treated a plague patient had to be interned for 20 days. It is to be regretted that the profession had not taken due interest in prophylaxis and was also accused of looking out too keenly for the honoraria. This attitude by the town authorities led to the taxation of physician's fees under a system intended to discourage exploiting the situation. The attendants and the inhumers who buried the plague victims were also keen after their stipends and to defray all of these charges the Pope sent a contribution of 10,000 crowns. The cotton believed to have introduced the contagion, was burned to allay the popular fear. Of 146 orderlies who attended the sick 87 contracted the disease and of this number 40 succumbed. Nine medical men were attacked and 5 died. A census taken before the malady appeared showed a population of 24,000. Over 6,000 are known to have died, while many other inhabitants disappeared; the census after the visitation showed but 16,000 people.

THE WASSERMANN REACTION IN PRIMARY SYPHILIS.

AN important original study of this subject by Grönroos appears in the *Acta Societatis Medicorum Fennicæ*, 1920, i, 2, in which the author's own conclusions are in part as follows: The positive Wassermann appears at the earliest at the close of the six weeks period which follows the day of infection, although traces of a positive may, rarely, be seen a week earlier. The usual time of appearance is during the seventh week in traces and the full reaction during the eighth or ninth week. The latest period of the appearance of the positive reaction is the twelfth week. If we reckon not from the date of infection but the date of the chancre the earliest appearance of the reaction is between the first and second weeks which follow the first appearance of the lesion; the full positive appears at the end of the second week. The average is an incomplete reaction three weeks after and a complete positive during the fourth week of the chancre. Not rarely the appearance is delayed until the fifth or sixth week, and even later. The interval between the first trace and the complete positive is about ten or twelve days. There are, however, a rapid or one week type (or less) and a slow type which requires two or three weeks. Some weakly positive cases die away to negative without maturing or remain at a low level indefi-

nitely. They form a transition between a sluggish type and an irregular type of reaction, in the latter of which after long delay the reaction finally becomes positive.

Not infrequently cases of positive reaction become negative and remain so for several weeks —so-called early latency, afterwards becoming positive with the appearance of secondary syphilis, the latter being usually delayed. The reappearance of the positive reaction may be very rapid in such cases. Other types of irregular reaction are seen and it may be falsely concluded that this behavior is due to treatment. As a rule when the initial reaction has become fully positive secondary syphilis appears—either at once or after a short interval. Rarely the roseola may appear while the reaction is still negative, but no further symptoms. In such cases the reaction suddenly becomes positive after a few days at most. All the foregoing statements imply that no treatment has been used. Treatment, even calomel by the mouth, may promptly bring the reaction to the negative phase.

The New Medical Poland.

Some years ago after the Germans had, as they believed, permanently conquered Poland from the Russians, the Medical Record published an editorial article on the Germanized Polish medical schools. Since then the fortunes of war have given Poland its independence and the resulting changes in the medical faculties and teaching should prove of interest. These have recently been outlined in an editorial in *La Presse Médicale* for January 31, 1920, xxviii, 9. There are at present in Poland two completely organized faculties of medicine, one being that of the University of Cracow, founded five hundred years ago, and the other that of Warsaw. In addition the first year studies of medicine are taught at Posen and Vilna, the latter school having been a great scientific center in which the Latin culture once flourished, until closed by the Russian conquest of Poland. The University of Vilna has recently undergone a striking renaissance. Finally there is a medical faculty at Lemberg or Lvov, but at present it does not function; and there is to be a new medical school in Lubin. To retrace our steps the present University of Warsaw goes back only to 1905, for it was in that year that some of the restrictions of Russian dominance were relaxed so that from a Russian institution it became quasi-Polish. This movement in fact extended through all of the Polish institutions of learning. There is at present no lack of students (Warsaw has 1,400 enrolled), but a marked shortage of teachers. The aim of the faculties is to combine the excellences of the French and German schools. The former Austrian Poland may be the slowest to recover from the war. Warsaw is splendidly equipped with hospitals and laboratories and the Medical Society of Warsaw has a fine library. The writer apparently is not informed as to exact conditions in the other medical centers. There is a Franco-Polish commission which functions in both Paris and Warsaw to maintain an *entente* between the medical men in the two countries. Leaders of the profession in France are of this commission, which includes such well known Poles as Babinski, Danysz, and Okinczyc.

Permanent Celialgia Following Dysentery.

This condition presents three forms, namely, (1) the flatulent, which is at the same time gastric and intestinal, with meteorism beginning soon after meals; (2) the coprostatic form, with difficulty at stool, which, although not bloody, takes place only every two or three days; (3) intestinal cramps, arising in either the left colic angle or sigmoid flexure in the morning or sometimes within five hours after meals. These disturbances are due either to reflex irritation or to a neuritic inflammation of the celiac plexus. Colitis of one or another type may likewise be present, particularly in the amebic form of dysentery. But when a colitis is present, the permanence or the frequent return to activity of the intestinal lesions is combined with the neuritis. This syndrome exists in a number of other pathological processes, such as locomotor ataxia, saturnism, oxalemia, alcoholism, and pneumococcia. Palpation over the so-called nodal points of Loeper and Esmonet is extremely distressing for the patient. The initial lesion and in particular the lesions of the intestine in bacillary dysentery are recovered from easily and rather quickly. The lesions of the solar plexus resist and may continue for weeks or months. As in the case of neuralgia of the trigeminus, which does not subside after removal of the offending tooth, the abdominal neuralgia will not disappear after the intestinal lesions have retrogressed, so that dyspeptic states, spasm, and pain continue. The treatment does not consist merely of rectal irrigation and a strict diet, but should also include antispasmodic and nervine therapeutics. Perhaps a small dose of antidysenteric serum might be given every three days, after the analogy of the treatment of diphtheritic paralysis. Loeper of Paris has resorted to this therapeutic measure in some cases with happy results. Belladonna, oily laxatives, and enemata of liquid vaseline often are sufficient for controlling the spasm and pain. Strychnine is contraindicated, as it awakens muscular reactions and its ill-effects are almost a positive proof of the spasmodic nature of the pain. Electrization has given good results. The high frequency current also renders real service and hot applications to the abdomen are always indicated.

Nervous and Mental Complications of Grippe.

Under this caption Courbon, who is at the head of an insane asylum, mentions (*La Médecine*, February, 1920, i, 5) as a complication of the pandemic of 1918, a special lesion of the mesencephalon located beneath the third and fourth ventricles in the gray nucleus and locus niger, which gave rise to a syndrome of fever, somnolence, and motor disturbances of the ocular muscles. This was the encephalitis lethargica of Netter. The fact that it was known before the pandemic is admitted, but the author's opinion is not thereby altered that lethargic encephalitis is grippal mesencephalitis. Among postgrippal psychoses the chief in the author's experience is a pseudoparesis which differs from

meningoencephalitis of syphilitic origin by its benign tendency. One sees a syndrome of forgetfulness, tremor of the tongue and fingers, embarrassment of speech and exaggeration of reflexes. The condition appears during convalescence without antecedent mental disturbance with the picture of asthenia, mental confusion, stupor, and more or less complete suspension of ideation and motricity.

News of the Week.

Medical School of the University of Alabama.—It is announced that on June 1 the Medical School of the University of Alabama, now in Mobile, will be removed to Tuscaloosa, where it will be reorganized as a preclinical college with a two-year course of study. This change was decided upon following the action of the Council on Medical Education of the American Medical Association in degrading the school to Class B.

New York Hospital Campaign.—The campaign for a new building and improvement fund for the Society of the New York Hospital, which operates the New York Hospital, the Bloomingdale Hospital, and the Campbell Cottages for Convalescent Children at White Plains, has been renewed, and a fund of $100,000 will be sought to meet a current deficit.

The Walter Reed General Hospital.—Plans have been made for the development of the Walter Reed Hospital in Washington into one of the main hospitals of the army and a nucleus of a medical center on the modern group or team system. Two additions to the main hospital building will be made to accommodate additional medical and surgical wards, a dental department, laboratories, an eye, ear, and throat department, and a dispensary. Some of these departments are now housed in temporary buildings.

Dr. J. J. Kindred of Astoria, L. I., has been appointed highway commissioner of Queens by the borough president.

Dr. John F. Ferguson of Brooklyn has been appointed a member of the New York Board of Elections by Mayor Hylan.

Maternity Hospitals Must Be Licensed in Ohio.—According to a definition recently made by the Ohio State Commissioner of Health, any institution in the State which admits maternity cases will hereafter be required to obtain a license. The definition given is that any place receiving women for care during childbirth is a maternity hospital, this including not only hospitals operated exclusively for maternity cases, but also a general hospital having a lying-in department or ward and private institutions accepting the case and management of women in childbirth.

The University of Vienna has been closed on account of anti-Semitic riots, which took place during the final week in April. The leader of the German student party has issued a statement to the effect that it is uncertain whether the students will permit the reopening of the institution, except upon condition of the exclusion of the Jews.

Dr. Markoe's Age.—In the obituary of Dr. James W. Markoe, published two weeks ago, it was stated that he was born in 1882. This was, of course, a misprint, as was evident from the context. He was born in 1862.

American Public Health Association.—The date of the annual meeting of this Association in San Francisco has been changed to September 13-17. The change was necessitated by the occurrence of a California State election on August 30.

A Life Cut Short by Prohibition.—It is reported in *The Sun and Herald* that Thomas Morris of Grand Island, Neb., died there recently at the age of 126 years. It is asserted that the statement as to his age is absolutely authenticated by the old family Bible which contains the record of his birth in North Wales on January 15, 1794. His death is attributed to the fact that he was no longer able to get his daily modicum of whiskey.

Asks $25,000 for a Ducking.—A German physician has brought suit against a number of his former neighbors in Osage County, Kansas, to recover $25,000 damages for alleged indignities suffered during the summer of 1918. It is stated that a number of citizens, outraged by his utterances, which were disloyal and pro-German, threw him into a water trough and otherwise hurt his feelings.

Changes in the Insanity Law Suggested.—Dr. J. F. M. Meagher, president of the Brooklyn Neurological Society, has issued a letter to the medical staff of the various State hospitals advocating a readjustment of the New York State insanity laws, not only for the welfare of patients, but for the protection of society. Insanity, as it is usually termed, is a medical, and not a legal problem. As the laws now stand, a judge or a jury has the deciding opinion as to whether a man is sane or insane; safe to be at large, or unsafe; and neither by education nor by training is either competent to decide. Not infrequently Dr. Meagher says, persons suffering from dangerous paranoid conditions are usually asked in court whether they are insane, and on replying in the negative are discharged forthwith! Some hope of relief from this deplorable state of affairs is afforded by the April additional Grand Jury which recently handed up to Judge Joseph F. Mulqueen in the Court of General Sessions a presentment expressing its regret over the death of Dr. James Wright Markoe, who was killed in St. George's Church, April 18, and recommending changes in the insanity law. The jury suggests that a petty jury at a trial be permitted to find a defendant "guilty, but insane." At present the verdict must be worded "not guilty, but insane." It suggests also that the law be amended so that a corps of physicians or neurologists be appointed as the only competent authority to certify to the court on insanity cases. These suggestions, if carried out, mean that hereafter neither lawyers nor laymen can qualify on a commission in lunacy. At present the law provides a commission composed of a physician, a lawyer and a layman appointed by the court.

Intestinal Pathology in the Functional Psychoses.—In the article with this title published last week, the caption for Fig. 4 on page 722 should read: Roentgenogram, taken after a barium enema, showing leakage at the ileocecal sphincter.

Bequests to Charities.—The will of the late Dr.

Wallace H. Dean of Springfield, Mass., gives $10,000 each to the Old Men's Home and the Good Will Home. It also gives 25 acres of land in the town of Blandford for a public park, and $20,000 for the erection of a town school building.

Public Health Poster Contest.—As previously announced, a prize of $100 is offered by the New York State Department of Health, through the bureau of venereal diseases, to the person who offers the best colored drawing which can be reproduced as a poster for use in the public health work of the bureau. The rules of the contest are the following: Drawings should be colored and may be made any size desired, but must not be smaller than 12 x 18 in. The winner will be chosen from among those whose drawings are received at the New York State Department of Health, Albany, N. Y., before 5 p.m., June 1, 1920, this being an extension of time of one month, made because of the intervention of the Easter vacation and examination time in many of the schools. Drawings will be returned if the artist will submit postage. It may be desired to purchase for use elsewhere certain of those drawings not winning the prize. The bureau reserves the right to reject all drawings if in the minds of the judging committee none satisfactorily meets the requirements.

Medical Society Elections.—The ECLECTIC MEDICAL SOCIETY OF THE STATE OF NEW YORK at its sixtieth annual meeting held in Albany, April 21 and 22, 1920, elected the following officers: *President*, Lewis B. Dawley, Westtown; *First Vice-President*, L. B. Gardner, Geneva; *Second Vice-President*, A. B. Wolf, Queens; *Third Vice-President*, E. G. Padgham, Geneva; *Secretary*, T. D. Adlerman, Brooklyn.

The WINDHAM COUNTY (CONN.) MEDICAL SOCIETY at its 127th annual meeting, held in Willimantic on April 16, elected the following officers: *President*, Dr. J. M. Perreault, Danielson; *Vice-President*, Dr. Fred M. Smith, Willimantic; *Secretary*, Dr. R. C. Paine, Thompson; *State Delegates*, Dr. A. D. Marsh, Hampton, and Dr. E. F. Perry, Putnam; *Councilor*, Dr. S. B. Overlook, Pomfret; *Censors*, Dr. T. R. Parker, Willimantic; Dr. C. E. Hill, Killingly, and Dr. W. H. Judson, Danielson.

The HILLSBOROUGH COUNTY (N. H.) MEDICAL ASSOCIATION, at its 15th annual meeting held in Manchester on April 20, elected the following officers: *President*, Dr. Clarence O. Coburn, of Manchester; *Vice-President*, Dr. C. E. Smith, of Grasmere; *Secretary-Treasurer*, Dr. P. F. Rock, of Nashua; *Executive Committee*, Drs. John C. O'Connor and George V. Fiske, of Manchester, and Clarence W. Milliken, of Goffstown.

Obituary Notes.—Dr. CLARENCE EMMETT PFEIFER of Columbus, O., died April 23 at the age of 46 years. He was born in Galion, O., and was graduated from the School of Medicine of the Ohio State University in the class of 1904. He served during the war in the medical corps of the army with the rank of captain.

Dr. WILLIAM HENDERSON RUDDICK of Boston, Mass., died from cardiac disease April 8, at the age of seventy-five. He was graduated from the Medical School of Harvard University in 1868. Dr. Ruddick was a veteran of the Civil War and of the Spanish-American War, and was a member of various state and local organizations.

Dr. WILLIAM DAWSON ROBINSON of East Orange, N. J., died April 13 in his 78th year. He was graduated from Bellevue Hospital Medical College in 1879.

Dr. P. W. F. CORNING, of Londonderry and Manchester, N. H., died April 13 aboard a Manchester-Boston train as a result of injuries received when the automobile in which he was riding was struck by that train at a crossing. Dr. Corning, who was born in 1872, was graduated from the Baltimore Medical College in 1906.

Dr. C. P. LINHART, of Columbus, Ohio, died at his home in that city, of pneumonia, on April 15, at the age of 59 years. He was a graduate of the Western Reserve University Medical Department in the class of 1882.

Dr. CALVIN WEIDNER, of Hartford, Conn., died at Sarasota, Fla., on April 12 after a long illness. He was born in 1867 and was graduated from Medical College of Indiana in 1893. After a period of study in Vienna he settled in Hartford, where he devoted his attention chiefly to otolaryngology.

Dr. LOUIS NOTT LANEHART, of Hempstead, L. I., died of heart disease on Sunday of this week. He was born in 1859 and was graduated from the Albany Medical College in the class of 1883. He was one of the organizers of the Nassau Hospital and was later one of the attending physicians of the Belmont Hospital of Hempstead. He was also health officer of Hempstead.

Dr. ARTHUR JUDSON BENEDICT of Newburgh, N. Y., died April 17. He was graduated from the University of Buffalo Medical Department in 1876, specializing in otolaryngology. He was a member of the American Medical Association.

Dr. HENRY SHERMAN KILBY, of North Attleboro, Mass., died suddenly April 10, at the age of sixty-eight. He was graduated from the Medical School of Harvard University in 1878.

Dr. E. L. EBERHARD, of South Whitley, Ind., died recently at the age of sixty-two. He was graduated from the Medical College of Ohio, Cincinnati, in 1880. He was a member of the American Medical Association.

Dr. SIDNEY FREEMAN WILCOX, of New York City, died April 19, Middletown, N. Y., while performing an operation in the Thrall Hospital. He had just removed a tumor from the patient when he dropped to the floor dead. The operation was completed by Dr. Moses A. Spivers, of Middletown. Dr. Wilcox, who was graduated from the New York Homeopathic College and Flower Hospital in 1880, was professor of clinical surgery in the New York Medical College and Hospital for Women. He was a Fellow of the American College of Surgeons, the New York Academy of Pathological Science, and other organization.

Dr. JOHN F. CANAVAN died in Bridgeport, Conn., on April 20, after a brief illness. He was born in Clyde, R. I., in 1888 and was a graduate of the Eclectic Medical College, Cincinnati, in 1913.

Dr. EZRA C. HARRIS of Springfield, O., died of heart disease on April 17, at the age of 75 years. He was graduated from the Sterling Medical College, Columbus, in 1876, and practised first in Clifton, going to Springfield in 1890.

Dr. BUFORD N. DUNAVANT of Memphis, died suddenly April 11. He was born in 1882 and was a graduate of the Memphis Hospital Medical College in 1906. He was formerly surgeon with the rank of major in the 115th Field Artillery.

Dr. DON D. GROUT of Waterbury, Vt., for eleven years head of the State Hospital for the Insane, died suddenly of angina pectoris on April 16. He was 71 years old and was a graduate of the University of Vermont College of Medicine in 1872.

Dr. GEORGE M. HOEHN of Cincinnati, died on April 21 after a long illness. He was born in 1852 and was a graduate of the Medical College of Ohio in 1885.

Dr. RICHARD J. P. GOODWIN of Malden, Mass., died April 19, after a long illness in his 83d year. He was born in Boston and was a graduate of the Harvard Medical School in the class of 1865. He served in the medical corps of the United States Army throughout the Civil War.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, April 15, 1920.

Ex-Service Tuberculous Patients.—The subcommittee of the Norfolk Insurance Committee at a meeting held in Norwich on April 10, reported with regard to discharged sailors and soldiers that they had recently had before them several cases of discharged soldiers who were demobilized as fit, but were subsequently found by their panel doctors to be suffering from tuberculosis. In each case Dr. Burton Fanning of Norwich, an authority on tuberculosis, had certified that, in his opinion the disease was attributable to war service, and his certificate, together with the evidence on which he relied, had been forwarded to the Minister of Pensions, with a view to establishing the committee's claim to a refund of the cost of institutional treatment. The medical advisers of the Ministry of Pensions, however, without disclosing any evidence in support of their conclusions, had declared that the disease could not be attributed to war service. The subcommittee felt that an important question of principle was involved in this procedure, which enabled the deliberate conclusions of an expert as Dr. Fanning was, who was in personal touch with the case, to be overridden by officials in London, who had not personally examined the patient, and who made no disclosure of the evidence on which the adverse decision was based. The subcommittee had made strong representations to the Minister of Health, in the hope not only that the specific cases referred to would be reconsidered, but that the present procedure would be radically amended.

A point with respect to panel practice of some importance to panel practitioners was also discussed at this meeting. The subcommittee reported with reference to panel druggists that, under the amended Insurance Act, so far as remuneration was concerned, the panel druggist would receive a considerable advance on the dispensing fees. The arrangements in connection with the dispensing in rural areas had been greatly modified. Under the old regulations a panel practitioner had the right to elect to dispense for insured persons who resided more than one mile from the nearest panel druggist. Under the new regulations, in effect, the practitioner has no choice, the decision resting either with the committee or the insured person. When the committee was satisfied that insured persons, by reason of distance or inadequacy of means of communication, would have "serious difficulty" in obtaining drugs and appliances from the druggist, the committee must require the practitioner to dispense. The subcommittee had decided on general principles that, *prima facie*, "serious difficulty" might be assumed to exist where a doctor and a druggist were not in the same locality. The committee therefore formally required the medical men in such localities to dispense for their insured patients. This, in effect, maintained the *status quo ante*. On the other hand, where there were a doctor and a druggist in the same locality, "serious difficulty" obviously did not exist, and the insured persons residing more than one mile from the nearest panel druggist must themselves decide to obtain drugs and appliances either from their panel practitioner or from a panel druggist. In the conduct of a Ministry of Health and of a Ministry of Pensions bureaucratic methods are necessarily in vogue, and it follows that the panel practitioner has to cope with a multitude of regulations which is by no means the least repugnant feature to him of the National Insurance Act. The panel practitioner loses a good deal of his independence, but if this is for the common weal, it matters little. However, it has yet to be clearly proved that the Act is in the interests of the general public. As for its benefit to the medical profession opinions among medical men differ. Indeed, it is a debatable point.

Sir James Mackenzie at St. Andrews.—Probably, in fact assuredly, no medical specialist, if so able an all around physician may be termed a specialist, has of recent years enjoyed a greater reputation in the Old and New Worlds than Sir James Mackenzie. Without exaggeration, his investigations into the cause of heart disease and the results thereof may be called epoch-making. When then this man in the heyday of his fame and success left London and betook himself to the "wee gray toon by the sea," St. Andrews, all who knew him personally or by reputation were amazed. However, astonishment has given place to comprehension and admiration, for he has a message to give to the world and great work to do on behalf of British medicine. His book, brought out a year and a half ago, "Future of Medicine," explains his views. He is a hard and fast advocate of the practice of preventive medicine and his means of prevention are to track down disease to its source and to attack it before it has gained a hold on the system. His theory is that, as every disease has early symptoms, if the earliest and lightest symptoms can be interpreted in terms of future danger the patient may be saved while others are waiting for the disease proper to manifest itself. This is one phase of the matter. The

other is concerned with the after histories of people examined. It is obvious that, in order to understand the significance of any symptom, one must know what happens to the people who show it. This may be the reason why St. Andrews was chosen for the work. As the medical correspondent of the London *Times*, April 9, points out, the old city is self-contained and its inhabitants tend to remain for generation after generation within its walls. Consequently, it should be possible in process of time to discover the ultimate significance of the so-called trivial signs of ill-health. As Sir James Mackenzie says: "It will take us many years to complete our survey, but when it is complete we shall have such a knowledge of the early processes of disease and the means of detecting them as must prove of infinite value. Knowledge of this kind simply does not exist today. The man who sees the earliest signs of disease is not the great consultant but the general practitioner." The outstanding feature of the entire scheme is that the work is founded on the general practitioner, and is essentially of a preventive medicine character. The general practitioner is enlisted in it and it is he who is carrying it on. The object at St. Andrews is to trace disease to its sources, to search for and find out the small hidden springs, those earliest subtle symptoms which are so difficult to detect and to which, up to the present time, little attention has been paid. In some respects, the endeavor may seem Utopian, but its principles are based on sound common sense. There are few diseases which come like "a bolt from the blue," or "a thief by night"—practically all, even in their most incipient stages, show some slight symptoms which if detected might be prevented from progressing. When men have learned what these symptoms are and have been trained to detect them, successful preventive treatment will be possible. It is interesting to recall that Sir James Mackenzie spent some of the busiest and probably the most fruitful years of his life in general practice. No one, therefore, is better able to place a correct estimate on the value of the general practitioner and his opportunities for investigating into the very beginnings of disease.

Next Year's Census in Great Britain.—Under the direction of the Minister of Health, the Registrar General is perfecting the machinery for the decennial census of the United Kingdom in 1921. Following precedent the enumeration will take place on the first Sunday in April, but for the first time it will proceed on lines which will enable easy comparison to be made with the statistics of the whole of the British Empire. Dr. Addison, the Minister of Health, is preparing the measures necessary for obtaining the authority of Parliament in the matter. Two bills are needed, one relating to Great Britain and the other to Ireland. As in 1911, so in 1921 the officials acting on behalf of the Registrar General will want to know the sex, age and occupation of everyone within their jurisdiction. The first general census of the United Kingdom was taken in 1801, and since then there has been a fresh numbering of the people every ten years with the following results:

	Population
1801	16,345,646
1811	18,509,116
1821	21,272,187
1831	24,392,485
1841	27,036,450
1851	27,724,056
1861	29,321,288
1871	31,845,379
1881	35,241,482
1891	38,104,975
1901	41,976,827
1911	45,365,599

The subjoined table shows what was the population of the various parts of the United Kingdom in 1911.

England and Wales.—Males, 17,448,476; females, 18,626,793. Total, 36,075,269.

Scotland.—Males, 2,307,603; females, 2,451,842. Total 4,759,455.

Ireland.—Males, 2,186,804; females, 2,195,147. Total, 4,381,951.

Thus there were 1,339,855 more females than males in the United Kingdom in 1911. From 1901 to 1911 the population increased by 3,756,508 persons.

Some Pathological Aspects of Tuberculosis.—Dr. W. E. Carnegie Dickson, lecturing recently at the Royal Institute of Public Health, mentioned the various opportunities which had come his way for studying tuberculosis. He laid stress on the need for reliance upon clinical examination quite as much as upon pathological tests, because a positive result in a sputum test for instance denoted an advanced case and clinical diagnosis should generally give a diagnosis much sooner. Pathologists should have a short clinical history of each case, because otherwise the value of results when they came to be compiled was lessened. Syphilis of the lungs is a condition more prevalent than generally recognized and this fact should be remembered. Clinically it often resembled tuberculosis. The affection of the lower lobes, spread from the root in a downward direction, is most usual, and *x*-ray plates may show fibrosis very similar to that of tuberculosis. Judging from his experience the approximate number of bacilli present in a sputum is a rough indication of the severity of a case, but this is a rule with many exceptions. His own figures for the last two years showed that pathologically there were more tuberculous cases among the out-patients of the chest hospital than among the dispensary out-patients in the same district. As for bovine tuberculosis, Dickson epitomized some of the pioneer work done at Edinburgh on the bovine bacillus. This work showed that in children the tonsils were frequently the site of infection, but such tonsils were not usually enlarged or clinically recognizable. The gastrointestinal mucous membrane and respiratory tract could be infected anywhere, but his autopsies on children showed that the glands of the ileocecal angle were most often infected, and in many cases were so large as to be palpable. This might aid in diagnosis. So far as mass infection is concerned, the milk supply of a district is most important. The

tuberculin reaction for cows is very fallacious. Sometimes the animals are too ill to react, in other instances unscrupulous farmers give a previous injection and so forestall any reaction. Questioned as to the theory of early infection producing immunity, Dickson considers this theory most dangerous. He thinks a patient more likely to be sensitized thereby. With regard to opinions recently expressed concerning the "flaring up" of old infections, he is more inclined to believe that reinfection is the cause of a new outbreak.

Cancer Research.—The decision to amalgamate the Cancer Research Department of the Middlesex Hospital and the Bland Sutton Institute of Pathology with the medical school of the hospital has been confirmed recently at a meeting of the Court of Governors of the hospital. It is of interest to note that the Cancer Research Department of Middlesex Hospital has been established for thirty years, but the hospital has had a cancer charity attached to it since 1792. The medical school dates from 1774, the hospital having been founded in 1745. The Bland Sutton Institute was erected in 1913. With regard to the amalgamation the secretary of the hospital says: "We are getting together a body of scientists of great reputation and, having regard to the value of the close connection between the research and the clinical side, the prospects of fruitful results from their work will be greatly increased by them acting together. That is the sole purpose of the amalgamation. The hospital funds will not be encroached upon in any way, each of the institutions having its separate income. Instead of the research work being done in watertight compartments it will now be all coordinated." The war gave a great impetus to medical research work and it is as a sign of the accelerated public interest in such investigation that the activity evinced at the Middlesex Hospital in cancer research may be regarded.

Obituary.—A very well-known medical scientific man has just passed away suddenly in the person of Dr. Albert J. Chalmers. Dr. Chalmers devoted his brains and all the energy of his adult life to research work in tropical medicine. He lived for some years in Africa, but in 1901 was appointed by the Ceylon Government to the post of Registrar to the Ceylon Medical College. In 1912 he left Ceylon and in 1913 accepted the Directorship of the Wellcome Research Institute at Khartoum in succession to Dr. Andrew Balfour. He worked there successfully and without cessation, until a few weeks ago, when he left the Soudan for a holiday accompanied by Mrs. Chalmers. They intended to return to England by way of India, Japan and America, but at Calcutta Dr. Chalmers was taken suddenly ill and died there on April 6. In the *Medical Press*, April 14, is an eloquent tribute to the deceased scientist over the signature "A. C.," which no doubt are the initials of Dr. Aldo Castellani, a coworker with him in tropical medicine and joint author with him of the well-known and most excellent "Manual of Tropical Medicine."* This obituary directs especial attention to one of Dr. Chalmers' investigations, "the paramount importance of which will be recognized in the future, and which will certainly become a classic." His original work on mycetoma is that referred to. Dr. Chalmers died from infective jaundice at the comparatively early age of fifty.

4. Loss of Both Eyes from the Exophthalmos of Hyperthyroidism.—Frank H. Lahey reports the case of a woman admitted to the ophthalmological service of the Boston City Hospital with a past history of admission as an out-patient to another hospital a year previously, where she had been treated for hyperthyroidism by means of *x*-rays. Following this treatment, her pulse came down, she gained in weight, and her general condition improved, but the exophthalmos continued to progress until edema and ulceration of her right cornea was such that she came to the Boston City Hospital, and enucleation of the eye was done. The author was asked to see her a month later on account of increasing exophthalmos and edema of the left eye, and it was decided to attempt by surgical measures to preserve her remaining eye. Because of the belief that recession of the protruding eye occurs after removal of the sympathetic ganglion on the affected side, the operation of removal of the superior cervical sympathetic ganglion was carried out, and at the same time the external canthus was incised to relieve the pressure of the lid edges. Progress of the edema continued in spite of these procedures, whereupon two days later the lids were sutured together, and still edema and ulceration continued until enucleation of the remaining eye became necessary.

2. Drainage and the Mercury Ion in Cystic Goiter.—G. Betton Massey describes this method of treatment, which he has employed for a number of years with uniform success, without setback of any kind. The method is the establishment of free drainage of the cyst by a small opening into the sac through the skin, converted into a temporary sinus by cathodic electrolysis, through which cauterant and antiseptic ions are subsequently diffused from a conductor acting as anode. The sac walls and cavity are obliterated gradually by repeated small diffusions of the ions by the direct current at intervals of three days, final healing of the cavity showing a minute, solid scar at the end of about seven weeks. This apparently bold procedure is made entirely safe from septic or other infection by the development of the mercury ion within the sac every third day, an ion that possesses great antiseptic value. There has been no rise of temperature or untoward incident of any kind, the author says, in any of the cases treated.

1. The Somatic Causes of Psychoneuroses.—Charles L. Dana takes exception to the purely psychogenetic theory of the psychoneuroses, as, for example, the assumption that the war neuroses were nothing more than defense states aroused by the subconscious desire to get away from the front. He believes that there are always physical as well as psychic factors in the causation of the psychoneuroses and that pathological reactions do not occur in anatomically and physiologically sound bodies. He supports his theorem by both experimental and clinical evidence, among the latter being the case of a lad of nineteen years who had suffered for five years from attacks of a nervous, hysterical nature and was thoroughly incapacitated for the duties of life. Within two weeks after beginning thyroid treatment he was practically well. He still has occasional relapses, but these are subdued by a return to the use of thyroid extract. Dana admits that there must have been behind the gland defect in this case some instability of the nervous centers, for there always is in such cases. But the case does demonstrate that sometimes a gland defect is present in the psychoses and that no amount of attention paid to mental conflicts, conversions, condensations, complexes, sense of inferiority or any other phases of the psychanalytic and therapeutic effort would be of much use as long as his internal secretions were working defectively. In discussing the physical changes that occur with more or less completeness in the psychoneuroses, the author refers to the explanation of certain brain functions based upon the hypothesis of the dendrites and their ameboid movements. It may be assumed, he says, that since the synapsis is a point at which the traveling nerve impulse has to pass over a break in anatomical continuity, it here meets its highest resistance. Some neural phenomena, therefore, might be expected to develop here just as light or heat develops when an electric current meets a specially great resistance. The synapses of the cerebral cortex are thought to be the seat of consciousness, and we know that the seat of the mental activities is not so much in the cell as in the conducting fibrillæ, and it is those that are most disturbed in functional psychoses. The functions of the cerebral nerve cell are trophic and perhaps mnemonic. The cell rapidly deteriorates and changes its content and form, but the nerve fibers are practically unfatigable, although they have as active metabolism as that of gray matter. These fibers are so persistently active because they are supplied with nourishment as well as with protection by the medullary sheath, except at the dendritic and peripheral endings; so we ought to expect exhaustion at the synaptic points sooner than in the cell or in the nerve itself. They would be also more exposed to the influences of toxins and fatigue products. When a person has a great emotional shock, and there follow tremors, speech defects, paralyses or anesthesias, it may well be because the synapses of certain groups of neurons functionally selected and embryologically of similar development are blocked by the torrent of impulses aroused by fright or pain combined with excess of epinephrin or other toxic material thrown into the blood. The elaborate psychologic mechanism or the psychoneurosis with its theories of conflict, repression, conversions, compromise formations, condensation - inversion, uncompensated feeling of inferiority, may exist, but all these are not always necessary, and they are always agencies which have to act through a neural mechanism. If this is sound we shall rarely if ever get any psychosis. One of the most obvious objections to this assumption of the somatic origin of psychoneuroses would be that if a monoplegia, for example, or other form of neurosis has an organic cause, how can it be cured by a single mental effort or by suggestion? To which one might reply that the organic change is in more than a majority of cases biochemical, yet as real as a sclerosis, brought on by a shifting of neural changes through attention or concentration on a certain object. In certain emotional and exhaustion states the stomach does not secrete juice, and in the same way the neurons do not transmit their currents. In emotional states the total of neutral or cerebral energies is massed in certain minor and major association groups connected with the particular form of apprehension or terror. By effort or volition or by a counteremotion the equilibrium may in certain cases be restored.

1. The Diagnosis of Disease of the Pancreas.—Sir Archibald Garrod, in this Schorstein Lecture, delivered at the London Hospital Medical College on February 20, placed the diagnostic indications of disease of the pancreas in three main groups. In the first are the clinical signs and symptoms, such as tumor, pain, tenderness, vomiting, cyanosis, and the like, and the signs of pressure upon neighboring structures. Secondly, one may detect signs of failure of external secretion, defective digestion of proteins, fats, and carbohydrates. Thirdly, indications of failure of internal secretion, of which glycosuria is at the same time the most important and the best known. Lastly, there are certain syndromes which clinical and pathological experience has taught one to associate with lesions of the pancreas. Thus the diagnosis of carcinoma of the head of the gland is often correctly made upon purely clinical evidence, and in cases of bronzed diabetes, with the enlarged cirrhotic liver and peculiar pigmentation of the skin, the pancreas is always implicated. Many ingenious tests of pancreatic efficiency have been devised, and each test has its adherents and each its critics who question its utility. From a consideration of these it is evident that practically every sign, symptom, or test may fail at times, and that in each individual case one needs to balance the quantity and quality of the evidence for and against a lesion of the pancreas.

3. The Electrical Stimulation of Nerves at Operation.—Noel H. M. Burke gives the results obtained and the lessons gained from observations during the years 1915 to 1917 at the Horton and Manor War Hospitals at Epsom in a series of some eighty cases. The conclusions and lessons drawn are as follows: (1) Every case should be tested, as a fair number of decisions are made easier by the information obtained and an unnecessary section of an undivided nerve may be thereby avoided. This was strongly brought home in a recent case, not included in the series, where the median nerve had been exposed high in the axilla. The surgeon, his assistants, and the writer all felt the mass of scar tissue into which the nerve was traced, and all thought they detected a definite end to the nerve course. On stimulation, however, contraction was obtained. Without this demonstration it is quite probable that the nerve would have been divided at its apparent cut end in order to make further dissection simpler. (2) Conductivity is conclusive evidence of physiological continuity of nerve fibers, as also is excitability below the lesion. (3) Improvement in conductivity or in peripheral excitability following imme-

diately after neurolysis is suggestive of only slight compression and possibly chemical nerve-block. (4) Absence of conductivity and of excitability, even after neurolysis, is not conclusive evidence of division, but is probably an indication of fairly severe nerve disturbance.

4. A Lesson of the War: Suppurative Middle-ear Disease.—H. Smurthwaite says that out of 5,000 odd cases under his care in the Throat, Nose, and Ear Department of the Military Hospital, Tidworth, during the year ending October 31, 1917, 890 were suffering from chronic suppurative ear disease. They all suffered from more or less deafness and were not fit for the firing line, but most if not all of them would have been "A" men, as far as their ears were concerned, had systematic and energetic treatment been carried out in the early stages of their disease. Every person with acute middle-ear inflammation should be put to bed and given a brisk calomel purge. If there is any nose or throat trouble this should have appropriate attention. Should the drum membrane be bulging, the external auditory canal should be thoroughly disinfected by swabbing with 1 in 4,000 flavine or 1 in 20 carbolic, and the membrane freely incised under general anesthesia; the incision should be made in the posterior quadrant just behind the handle of the malleus and running crescentically down to below the tip. Gentle use of the Politzer bag will open the Eustachian tube and force the fluid out of the middle ear. This fluid is then mopped out of the canal; a pledget of cotton-wool soaked in flavine is placed close up to the drum, but must cause no pressure. It should be changed every few hours. The writer has sometimes plugged the canal lightly with wool soaked in 50 per cent. rectified spirit, which can be increased in strength if it causes no excoriation. At each dressing politzerization should be carried out or the fluid extracted from the middle ear by gentle suction. For the pain, which is sometimes very acute, glycerin of carbolic, 10 grains to 1 oz., is useful; a few drops warmed in a teaspoon and instilled into the ear, or a few drops of chloroform, will give relief; hot fomentation over the mastoid and auricle is always very soothing to the patient. There is always some postnasal catarrh, and a warm inhalation of compound tincture of benzoin every two hours will relieve the congestion of the lining of the mouth of the Eustachian tube and help the necessary drainage. Pain in the ear should never be passed over. It may only have its origin in a carious molar tooth or hard cerumen in the external auditory canal, but it is Nature's danger signal, and should ever be regarded. The object of the paper, Smurthwaite says, is to call attention to the great prevalence of chronic suppurative otitis and to urge the prompt treatment of acute ear disease in order to prevent the disabling chronic suppuration.

2. The Effect of Arteriovenous Fistula upon the Heart and Blood-Vessels.—Mont R. Reid reports the continuation of experimental and clinical studies begun in 1914 with Professor William S. Halsted. The animal experiments are summarized in tabular form. Fourteen clinical cases are briefly reported and also tabulated. From these observations the following summary is drawn: 1. An arteriovenous fistula of long duration usually causes dilatation of the artery proximal to the fistula. This dilatation may extend as far as the heart. 2. Marked cardiac disturbances may result from an acquired arteriovenous fistula of long standing. They are hypertrophy and dilatation, with eventual cardiac decompensation. 3. The wall of the vein involved in an arteriovenous fistula becomes hypertrophied. Although the vein on the proximal side of the fistula does not increase markedly in size, its wall shows a greater increase of elastic tissue than the wall of the vein distal to the fistula. 4. The venous blood pressure is increased in the part of the body distal to an arteriovenous fistula. When the fistula is cured the pressure returns to normal.

Rats and the Plague in Senegal.—It may be recalled that when the plague appeared in Dakar in 1914 it first assumed the lung form and seems to have been imported only as plague pneumonia. Only later did the rodents suffer and cases of the bubonic type become conspicuous. Since that period there has been no known importation, but according to Laveau an occasional recrudescence of the disease *in loco* attributed to the rats; in fact, the plague may now be regarded as endemic. In order to determine the part played by this animal 354 of them captured in a plague focus were examined and found intact with the exception of one great field rat which harbored a bacillus, beyond doubt *B. pestis*. The rat is doubtless both the reservoir and carrier of the disease to man. Recrudescence of the disease, endemicity of the disease in man, are dependent on fluctuations of the bacillus in the rats. At present the Danysz virus is doing much to exterminate them, but it must be used more extensively. The subject of the flea as the exact agent of transmission is hardly mentioned, being evidently taken for granted. No special measures against the insect are mentioned, for it is deemed sufficient to wage war against the rat. One member of the Society of Exotic Pathology before which Laveau's paper was read believed that the rat fleas should also be studied and classified.

Acute Poisoning from Bismuth Subnitrate.—Constantinesco and Jonescu mention as preliminary that bismuth poisoning due purely to bismuth is commonly called an impossibility. Given bismuth salts of guaranteed purity and there is no limit to the quantity which may be ingested with impunity in *x*-ray work. In apparent bismuth poisoning one must of course find the true motivation of the symptoms, whether these are due to an impurity like arsenic or to some other and extrinsic cause. In a case in point a young man with severe and persistent pain referred to the stomach, of long duration and appearing two hours after meals, subnitrate of bismuth for *x*-raying was used in the absence of the subcarbonate and of barium salts. Three teaspoonfuls of the subnitrate were swallowed in a half pint of milk. Nothing developed after the experience until Epsom salts were given by oversight in the evening. When these acted some time in the morning there was much nausea and prostration and the patient collapsed at stool. The *x*-ray examination had been negative. The stools were black with bismuth. At nine a. m. the patient was seen by the visiting physician to be in a state of collapse, cyanotic and algid with subnormal temperature. Theobromine was given but the condition became aggravated with the development of tonic convulsions and fixed pupils. Venesection was practiced and the blood showed cyanosis but coagulability was normal. Serum, adrenaline, camphor and caffein were given and next day the condition of the patient was nearly normal. The blood was subjected to a spectroscopic examination and chemical tests. The bismuth was analyzed and found pure. There was no obstacle in the gastroenteric tract which could have led to stagnation. The spectroscope showed a special band between the two absorption bands characteristic of oxyhemoglobin which was put in association with the toxic manifestations. The blood was positively free from bismuth but contained nitrous acid. But nitrite poisoning should have caused the formation of methemoglobin and this was not found. Instead apparently the oxyhemoglobin had been transformed to nitrohemoglobin and reduced hemoglobin. In any case bismuth subnitrate may be toxic if anything occurs to change the nitric to nitrous acid. In this case the dose of salts may have been responsible, although the mechanism is obscure.

Historical Beginnings of Psychopathology.—Cabanès quotes the historian Littré extensively on the history of medicine. The latter claimed that science is the "child of the age" and that all knowledge must be tested in the light of the past. Littré himself was a medical man and once refused the chair of medical history at Paris. He threw much light on the nature of apparitions as related in past centuries and of the choreomania or dancing madness which occurred in epidemics. Only the hypercritical fail to agree with him in his views of these subjects. False accusation in connection with demonology and witchcraft was another of his favorite studies and he showed the connection of these phenomena with modern hysteria. He foretold accurately that the history of medicine would receive its dues in the twentieth century. The history of psychopathology is barely seventy-five years old.

In 1836 Lelut wrote an article on the "demon" of Socrates which initiated our modern knowledge. According to Littré, the greater subject of the psychology of history which comprehends the lesser was also touched on by Lelut. Both individual and collective psychology are necessary for the comprehension of history. Studied by the light of modern knowledge we can understand that the alleged victims of the Furies were victims of one or another type of psychosis, perhaps sensorial (hallucinatory), or simply maniacal or motor. The visions of Swedenborg, the terrors of Pascal, find their counterparts in all ages among psychotic subjects. Brierre de Boismont, who published his celebrated work on hallucinations in 1845, acknowledged his indebtedness to Lelut. A contemporary, Calmeil, wrote on the psychology of the religious movements of the XV-XVIII centuries. Moreau of Tours then advanced the view that genius is a neurosis—a sort of acme of intellectual power which is supernormal. Lamartine stated that genius contains the element of self-destruction and madness "as the fruit carries the worm." Moreau was the first to understand the insanity of certain historical characters, but today, so marked and so satisfactory has been the progress in psychopathology, the author says, that the greater part of the mad geniuses have been correctly labeled and we know the precise kind and degree of their alienation.

Gazette des Hôpitaux.

March 23, 1920, xciii, 29.

Is Diabetes Curable?—Laumonier gives a joint review of recent articles on the cure of diabetes. The question, he states, is embarrassing, for there are numerous types of the malady and it may not be possible to control the cause of some of them. In the absence of causal therapy cure must be relative. It has been stated of late that glycosuria may be a defense reaction which should not be antagonized directly. To suppress the diet-carbohydrate is a method which goes back to Bouchardat, but this can hardly be called curative. It is a prophylactic of acidosis and to that extent should be practised to a certain degree. The danger of reduction of the forces from underfeeding has been checked by determining the carbohydrate tolerance in certain special plans of diet, as in the oatmeal cure, but the tolerance of the individual is not a constant but a variable. The idea of fasting outright originated with Guelpa, but he has received little credit for it which has gone to Allen and Joslin. Guelpa added purgatives and his idea was really to combat autointoxication rather than glycosuria. The principle involves several days of fasting and purging followed by a vegetable diet in the beginning. The Americans do not use purgatives and allow alcohol as a substitute for carbohydrate. He speaks of the results attained by Allen and Joslin as "mediocre," which appears to show that he is unaware of the showing obtained under favorable conditions. He also seems unaware of the fact that Kellogg of the United States gives full and ample credit to Guelpa for having been the first to introduce the fasting cure into therapeutics in connection with personal experience at Battle Creek.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Seventy-first Annual Session, Held in New Orleans, April 26-30, 1920.

(Special Report to the MEDICAL RECORD.)

(*Continued from page 764.*)

SECTION ON MEDICINE.

First Day—Wednesday, April 28, 1920.

DR. JAMES S. MCLESTER OF BIRMINGHAM, ALA., IN THE CHAIR.

Chairman's Address.—Dr. JAMES S. MCLESTER delivered this address which consisted in a discussion of clearness in medical speech. He said that when Polonius asked Hamlet "What are you reading, my lord?" Hamlet replied, "Words, words, words." Anyone who had been an officer of this section for five years could not fail to recall many splendidly conceived and brilliantly presented papers, but many things that he recalled, if his memory was good, were little more than words. There could be but one valid reason for appearing before the section and that was if a man had something worth while to say. He must be able to tell of some carefully planned and executed original investigation, must be able to establish some new facts, or must give some such complete summary in some particular field as would justify deductions of value. Yet the fulfillment of these requirements was insufficient to give an appreciative audience. The presentation should be clear and easy to follow, requiring the least amount of effort on the part of the hearers. It should be brief. It had been shown that a carefully written article could present an amazing amount of material in an exceedingly brief space of time. In writing a paper there should be few preliminaries; the writer should come to the point, omitting unnecessary details and repetition. He should awaken an interest in his subject else it would be difficult to follow his arguments, his ideas would not be grasped, and his conclusions would soon be forgotten. Medical literature to be followed with sustained interest required that superabundance of detail be avoided. There should be a striving for unity, clearness and coherence of thought. Clearness of composition depended upon clearness of thought. Attention should, of course, be given to the careful construction of sentences and paragraphs. For fear of being misunderstood Dr. McLester said he hesitated to compare the medical writer to the advertisement writer, but the advertisement writer knew how to put a great deal in a few words, to put the emphasis at the right point, and adhered to the main idea in order to hold his reader's interest and be really understood. Many medical writers did not succeed in these points because they did not try. It should be remembered that genius has an infinite capacity for taking pains. Lines that ran easily and smoothly and apparently without effort were often the ones over which the writer had worked most laboriously. A summary embodying the author's conclusions was always most valuable for it enabled his audience to grasp in one concept all that had been said, and when published it told the busy reader whether the article contained the information for which he sought. The title would be accurate, expressive, and brief, and in choosing a title one should remember that it would have to be indexed. Many a well prepared paper had failed to elicit interest because of poor enunciation or too rapid speaking. Speaking rather than reading should be encouraged. The value of illustrations and charts was recognized, but charts and tables should not be too complex to be readily grasped. Illustrations should be graphic and well arranged and unnecessary detail omitted. Discussions should be confined to the subject dealt with in the paper, should be brief, go directly to the point, and should avoid repetition. A man, no matter how much he might be interested, should limit his discussion to two, or at most three papers at a session.

The Clinical Interpretation of Basal Metabolic Rate Estimations.—Dr. HENRY S. PLUMMER of Rochester, Minn., read this paper in which he defined basal metabolism, showing that it was in fact the rate at which we lived. The rate of metabolism was largely due to the amount of thyroxin which was acting on the cells of the tissues. The thyroid under normal conditions regulated the production of energy through the action of thyroxin on the tissue cells, that was, the thyroid controlled metabolism, and the basal metabolism rate of the individual depended upon its activity. Early in 1917 they had begun to study the respiratory exchange under Boothby and Irene Sanford, and 10,000 basal metabolism estimations had been made. The fluctations of the basal metabolism from the normal had not up to that time much clinical significance. Variations of plus 10 and minus 10 were considered as within normal range. Among conditions which showed metabolism rates above normal were hyperthyroidism, adenomatous thyroid, exophthalmic goiter, hyperpituitarism, and beginning cardiac decompensation with edema and high blood pressure. The administration of thyroxin was always followed by increase in basal metabolism. A clearly established group of cases in which the basal metabolism was below normal were myxedema, cretinism, idiopathic and postoperative disturbances of nutrition, inanition and certain forms of psychoneuroses. The basal metabolism rate was particularly useful in differentiating exophthalmic goiter from psychoneurosis. In exophthalmic goiter the basal metabolism did not remain below 20 for any great length of time. In psychoneuroses the rate fluctuated greatly. In adenomatous thyroid cases a rate of plus 20 might persist for months and yet there might be no clear cut definite physical symptoms of hyperthyroidism. Few of such cases came under observation under thirty years of age, a fact of great help in arriving at a diagnosis. The basal metabolism estimations were of the greatest value in differentiating a cardiac syndrome and hyperthyroidism associated with adenomatous thyroid tissue.

Dr. EMIL GOETSCH of Brooklyn, N. Y., said that Dr. Plummer's results were based on an extensive experience and for that reason must carry great weight. The basal metabolism rate was a test *at one time* of the degree of thyroid intoxication. In other words one might have a thyroid intoxication that was not in one of its active phases and then it would be impossible to detect the fundamental disease by means of the basal metabolism test. Epinephrin hypersensitiveness served to indicate hyperthyroidism in cases in which the basal metabolism was normal. Epinephrin hypersensitiveness was persistent whether the patient was in an active state of hyperthyroidism or was passing through an inactive phase. In some cases of exophthalmic goiter the degree of thyroid activity was not demonstrated by the metabolic rate. Other ductless gland disturbances might also affect the metabolic rate.

Dr. L. G. ROWNTREE of Rochester, Minn., said the chief factors affecting basal metabolism were the extrinsic ones, such as food and exercise, and the intrinsic ones, the endocrine system and chiefly the thyroid gland. Since the thyroid gland was the particular regulator of metabolism it was evident that to get fundamental information regarding it one must study the basal metabolism. Their studies of 300 or 400 cases gave results identical with those of Dr. Plummer, although their series was much smaller. The epinephrin test was introduced ten years ago by Eppinger and Hess and was an index to the balance of vagus and sympathetic tone in the organism, and since disease of the thyroid might depend upon the balance of the vagus and sympathetic there was no conflict between these two tests; these should not be rivals but should complement each other. In some of their work they had found changes in the basal metabolism during menstruation and this should be taken into consideration in the study of basal metabolism rates in women. In the future the basal metabolism rate would be of tremendous value in the diagnosis, prognosis, and treatment. It was now of the greatest value in hyperthyroidism, myxedema, Graves' disease and toxic adenoma.

Dr. NELSON W. JANNEY of Santa Barbara, Cal., said their experience coincided in a small degree with that

of Dr. Plummer, in regard to the great advantage of this laboratory method in certain cases of the thyroid type. This method was in medicine to stay. It would be used in clinics and offices. It was the best gage of thyroid function we had. It was much more valuable than blood sugar estimations and certainly better than the adrenalin tests. One could not use it as an absolute guide as there were certain incipient cases of hyperthyroidism and Graves' disease that did not show a definite rise in metabolic rate. In certain cases of cretinism in which the basal metabolism rate had been brought to normal a corresponding disappearence of clinical symptoms had not occurred, so it was not an absolute criterion as to thyroid treatment. The study of basal metabolism would in the future probably be of greater interest in connection with treatment of diabetes.

Dr. PLUMMER, in closing, said he had been forced to use generalities but there were many exceptions. He did not think there was such a thing as an exophthalmic goiter without a basal metabolism rate above normal. They had found no case of hyperthyroidism in which the rate was not above normal.

The Nature of Fever.—Dr. ROLLIN T. WOODYATT and Dr. WILLIAM D. SANSUM of Chicago presented this contribution which was read by Dr. Woodyatt, who described experiments in dogs in which dehydration fever was produced. The injection of three or four grams of glucose per kilo body weight in animals or man produced glycosuria of high degree together with heavy diuresis. If glucose was injected in concentrated solution there was a loss of water and a loss in weight. After dehydration to a certain degree there was an increase in frequency and depth in respiration, chills, and fever. In one animal a rectal temperature of 125.6° F. was produced and in a number of animals the temperature reached 113° to 115° F. In attempting to explain the phenomena it was suggested that glucose tended to increase metabolism. The experiments were then repeated with salts and as dehydration proceeded the temperature rose as when the glucose was used. It was also found that fever was not produced unless there was dehydration. Experimental fever might be produced by changing the state of the water in the body without reducing the total quantity. These dehydration fevers were comparable with ordinary toxic fevers in the clinic. To find whether sugar and salt bore any relation to the fever centers in the brain, these centers were cut off; this made no difference in the production of the dehydration fever. The practical deduction was to prevent the patient from becoming dehydrated. In order to retain the body at a normal temperature a certain water reserve was necessary.

Dr. ALEXANDER LAMBERT of New York recalled cases of sunstroke that occurred during very hot weather in New York and cited one case in which the temperature rose to 122.4° F., the patient living four hours. He had seen patients with a temperature of 115° F. in sunstroke recover. At this time they had 800 cases of sunstroke. Among 200 of these possibly 50 per cent. had a temperature of 110° or 112° F. It was a curious fact that many of these patients were taken with sunstroke after a hearty meal and it was a question whether protein absorption was a factor. It was interesting in these cases that they did better when the temperature was brought down to 102° F. than when it was brought down to normal.

Dr. L. G. ROWNTREE of Rochester Minn., referred to work they were doing in relation to diabetes insipidus and water balance. In some patients with diabetes insipidus who might be passing ten or twelve liters of water a day the amount might be reduced to one and one-half or two, the water having been changed in some way so that the patient did not excrete it and as a result there was edema and headache. It seemed that there was some endocrine influence that interfered with the availability of water.

Dr. FRANCIS M. POTTENGER of Monrovia, Cal., said he was interested in the cause of the temperature and called attention to the fact that there was a peripheral mechanism active in producing temperature, namely, the lateral ganglia, and he wondered if dehydration might not produce an influence on these ganglia.

Dr. WOODYATT, in closing, said that dogs had recovered after a temperature of 108° F. He was glad Dr. Lambert had mentioned the temperature of 122° for he had hesitated to mention the experiment in which the dog had a temperature of 125° lest it be thought erroneous. With respect to the possible peripheral action on the nervous system, there was no question but that the vasomotor mechanism might be disturbed by various substances, but that had been a non-productive theory and it had not been possible to subject it to experiment. The one thing that was definitely brought out was that the fever came and went with the fluctations of the water balance.

Types and Treatment of Pellagra.—Dr. STEWART R. ROBERTS of Atlanta, Ga., presented this paper in which he said that two cases of pellagra were reported in America in 1864 and one by an Italian in 1883. Since that time the disease had been increasingly studied and reported until it was now practically found in every state in the Union and from Canada to Chili. There were as clear cut cases of pellagra in Maine and Massachusetts as in Texas. The practitioner everywhere should be on his guard to recognize this disease when he met it. From 1902 to 1920 statistics showed about 500,000 cases of this disease and 50,000 deaths in the United States alone. Among causes of death in 1916, it ranked fourth in Mississippi and third in Alabama. It showed years of increase, years of great severity, and years of decrease. In 1919 it had shown an increase in only one State and that was Kentucky. The disease was on the wane as regarded the number of cases and this was explained by the early widespread knowledge of the disease and Dr. Goldberger's work emphasizing the importance of improper and unbalanced diet as its cause, and of a proper and balanced diet as its cure. There was no evidence of insect infection or transmission. Severe types of the disease were becoming rare. It was not advisable to depend too much on a symmetrical dermatitis to make a diagnosis; they were coming to depend more upon constitutional symptoms. There was some question as to whether the disease was due to vitamine deficiency, protein deficiency, or deficiency of mineral ash. It was no longer believed that the disease was caused by corn. The diet that had been found effective was one composed of lean meat, eggs, butter, milk, and vegetable proteins. The disease was not only found among poor people but among the better class of people who had an abundance of food within their reach but had an antipathy to a well rounded diet. Of 25 private patients coming under the writer's observation only four were men. Drugs were of minor importance in the treatment of this condition. In order to carry out the proper dietic treatment it was essential to get the cooperation of the patient.

Dr. MARVIL L. GRAVES of Galveston said Dr. Goldberger's work was the best yet produced on the subject of pellagra. Dr. Goldberger had produced a certain form of dermatitis in persons on a limited protein and high carbohydrate diet but that did not prove that this was the cause of pellagra. While he was in accord with the reader of the paper, he did not feel sure that types of pellagra had changed, but they had diminished in intensity. A decade ago there was the tripod of symptoms, the symmetrical dermatitis, the gastrointestinal syndrome, including stomatitis and the nervous phenomena, particularly insomnia with depression. The number of cases of that form of the disease was decreasing and they were seeing at the present time two types of cases, namely those presenting gastrointestinal and those presenting nervous symptoms.

Dr. ALLAN EUSTIS of New Orleans said he had probably produced the first case of experimental symmetrical dermatitis in 1912 in a patient on a limited protein diet for the treatment of asthma. This patient had neglected to take green vegetables though they had been included in the prescribed diet. In this case there was no stomatitis and no diarrhea but there was evident undernutrition and a cure was effected by dietetic measures. Dr. Eustis cited the case of a woman under his care at the present time who had developed pellagra on a low protein diet, having adhered to a diet of hominy and coffee though she had abundant means. It was a question whether one was justified in making a diagnosis of pellagra on the basis of a symmetrical dermatitis, even if there was stomatitis, without ner-

vous manifestations and gastrointestinal symptoms.

Dr. Henry S. Plummer of Rochester, Minn., stated that he had seen a number of characteristic cases of pellagra but was not familiar with the milder type of the disease. The cases he had seen had had basal metabolism rates of 20 and 24 below normal. In a series of cases that he had never reported there was a group of hysterical dysphagias who simply would not swallow and who strained their food through cheesecloth, and as a consequence of the unbalanced diet taken in this way had developed pellagra. He found that by slipping a filiform down the throat of these patients and telling them they would be able to swallow the next day he had succeeded in getting them back on a mixed diet and they had recovered.

Dr. George Dock of St. Louis said that in a pellagra colony in the Austrian Tyrol one saw no skin eruptions. If one waited for a skin lesion he would never make the diagnosis of pellagra in many cases. The diagnosis might be made on the condition of the mucous membrane of the mouth and the general cachectic condition of the patient. It was well to remember that there were many varieties of skin disease; some were deficiency diseases and some were not.

Dr. Sheridan of Columbia, Tenn., called attention to the fact that pellagra was not a modern disease as we had been taught. He recalled cases thirty and thirty-five years ago in his work. One-half of his cases showed no dermatitis; the symptoms were usually nervous and mental, the original pathology being in the central nervous system, and the gastrointestinal symptoms came next. He felt sure many cases of pellagra were overlooked.

Dr. Stewart R. Roberts of Atlanta said that the fact that the basal metabolism in pellagra was low was to be expected because these patients were weak, had been taking little food and had low blood pressures. If at present we waited for a dermatitis to make the diagnosis of pellagra many cases would be missed. The greatest science was common sense and the greatest test was clinical judgment and clinical results. Through the work of Goldberger the time had come when we could look a pellagrian in the face and give him some encouragement of improvement on the basis of a mixed diet of 3,000 or 4,000 calories daily.

The End Results of Focal Infections.—Dr. Bryce W. Fontaine of Memphis, Tenn., presented this contribution in which he gave a brief history of the literature of focal infection and described his personal experience with 100 cases during the past two years. In the past there had been a failure to recognize focal infection and remove the focus; now the pendulum had swung too far the other way. All other possible causative factors should be excluded before concluding that a given condition was due to focal infection. The conclusion that the cause of the symptoms complained of in the series of cases reported was due to focal infection seemed demonstrated by the fact that the removal of the supposed focus of infection was followed by relief of the symptoms which was not followed by their recurrence. In the writer's series of cases the most common location of the focus of infection was the teeth, affected with such conditions as pyorrhea, granulomas, apical abscesses, etc. The tonsils were second in importance as the seat of infection. The sinuses were less frequently the seat of infection, but of the sinuses, the maxillary was most frequently involved owing to its proximity to the teeth. Pain in the muscles of the shoulders and chest was the most frequent symptom. Fever, seldom over 101° F., was secondary in importance, occurring in 18 per cent. of the cases and not often accompanied by chills. A few cases complained of night sweats. Chronic headache was present in four per cent. of these cases and anemia in four per cent. The blood in a large percentage of the cases showed a moderate reduction in hemoglobin and in the erythrocytes with a normal leucocyte count. Six cases showed achylia gastrica estimated by the fractional method.

Dr. Frank Billings of Chicago commended the common-sense rational viewpoint of the writer. He said he hoped he would not be obliged to carry the sins of commission practised on the people of this country because he had had something to say about focal infections. Focal infection was a principle which had come to stay because it contained a truth, but like every truth in medicine it had its limitations. Those who had not thought what the term meant had failed to grasp the fact that a focus of infection was different from focal infection. A focus of infection might give rise to focal infection or intoxication. By infection was meant the invasion of the body by microorganisms that had the power of reproduction and the power of producing reactions which produced abnormal phenomena which produced the clinical manifestations of disease. Most of the failure in the treatment and management of patients who suffered from what might prove to be focal infection was due to the fact that the operating surgeon or the physician in charge removed the focus, which might be the right one, and then neglected further management of the patient. If what he had said was true, namely, that focal infection meant invasion of the body by microorganisms in the tissues of the body, the operation had simply prevented more organisms from entering. As to results, focal infection was usually an invasion of the tissues and blood stream and produced results dependent upon the character and virulence of the organisms. They remained there if the defenses of the host were not sufficient to kill or drive them from the body. This being true, the removal of the focus in chronic infective arthritis would not greatly benefit the patient or would not benefit the majority of them. The duty here was to build up the resistance against the invaders by methods employed for the restoration of the blood vessels and for this purpose the methods of physiotherapy were suitable. The use of antigens in the form of dead bacteria had not proven satisfactory. He had used them controlling the work with all the knowledge at our disposal; he had used autogenous and non-autogenous, activated and non-activated antigens and those who did not receive them did as well as those who did. Foreign protein antigen injected intravenously appeared in the hands of some to have given success, but immunologists could not tell anything about this procedure. When one employed foreign protein antigens he was taking the health and possibly the life of his patient in his hands. He would not say that they should not be used but they should be approached with rare judgment and discretion.

Dr. Joseph H. Pratt of Boston said this subject was a complex one upon which there were no careful clinical studies. Dr. Fontaine's paper was a distinct contribution to our knowledge of the subject, since it was made by a man who was a careful clinician. The special value of that paper lay in the fact that the end results were given after the writer had followed the cases for a year or more; too often only the immediate results were given. The practice of sending patients to the dentist to have their teeth removed for the purpose of eliminating a focus of infection and then turning them adrift without further care or treatment was to be condemned. Dr. Pratt cited cases in which, owing to mistaken diagnoses, patients were subjected to unnecessary operation for the removal of a supposed focus of infection, and others in which failure to recognize the relation of symptoms to a focus of infection had led to very serious results.

Dr. Frank C. Wynne of Indianapolis said that in the older days it was the custom to blame the liver for every ailment for which the cause was unknown; later malaria was used as the cloak to cover the sins of ignorance, and now the term of focal infection was being used in the same way. The blame for obscure conditions should not be placed on the tonsils or teeth until after a careful clinical investigation. The habit of blaming everything the cause of which we did not know upon the tonsils or teeth was the sin of clinical medicine today. In searching for a focus of infection one should not be content to look only at the tonsils or teeth but should search the body critically.

Dr. William S. Thayer of Baltimore urged care in the selection of the specialist called upon to perform operations for the removal of foci of infection. Delicate surgical operations were being practised for the removal of foci of infection which were not common a few years ago and which required a high degree of surgical skill such as only the best trained men possessed. There were many surgeons. Dr. Thayer said, whom he would be willing to have take out his appendix

but few that he would trust to take out his tonsils or operate on ethmoid disease. Patients from whom foci of infection were removed should be carefully followed afterward. The common practice of removing all teeth supposed to be responsible for focal infection was barbarous in the extreme. The reckless manner in which teeth were extracted was a scandal to the profession. Gingivitis and pyorrhea were not properly treated as a rule; the cure of these conditions often required hours of work over long periods of time. Teeth should not be extracted simply because they were dead. Where apical sclerosis was present the teeth could be treated by opening and curetting; in this way many teeth that were now sacrificed could be saved in young and well-preserved people. If a tooth was extracted and the patient received no further care the suppurating cavity closed and the focus remained.

Dr. SOLOMAN of St. Louis emphasized the importance of searching the lower part of the gastrointestinal tract the colon, the sigmoid, and the rectum, for foci of infection.

Dr. CARLETON DEDERER of Bay City, Mich., declared himself on the side of the enthusiasts on the question of focal infection and described the work being done in a clinic in Bay City where they made it a routine practice to search for the focus of infection in the teeth and tonsils and to remove such foci before removing other supposed foci of infection.

Dr. FONTAINE, in closing the discussion, emphasized the fact that he made the diagnosis of focal infection with great reluctance and only after every other means of arriving at a diagnosis had been exhausted, and after consultation with those skilled in their special lines of work. There had been no recurrence in any of the cases he had reported.

The Clinical Diagnosis of Obstruction of the Hepatic Veins.—Dr. CHARLES W. HOOVER of Cleveland presented this paper in which he related the case of a man in whom marked enlargement of the liver occurred over night, with typical iced liver, peritonitis, and local phlebitis. He made the diagnosis of obstruction of the hepatic veins. He became interested in the condition and had collected several other cases. He stated that obstructive lesions of the hepatic veins were described by Budd in 1857 and by Frerichs in 1861, but the first clearly formulated conception of the lesion was given by Chiari of Prague in 1899. The largest experience with the condition described in the literature was that of Nishigawa (*Mitt. a.d. med. Fakultät d. Kais. Univ.*, Tokyo, August 20, 1919) who described ten cases, which were reviewed quite in detail. In the entire literature only 30 cases had been reported. In these ten cases there was not only obstruction of the hepatic veins but of the vena cava as well. In these cases cirrhosis and ascites had been ruled out. Obstructions of the hepatic veins were rarely sought for by either clinical or pathological examinations. The clinical symptoms were those of blood stasis within the liver without any evidence of cardiac incompetence. There was a total want of evidence of any disease of the hepatic parenchyma. All the objective signs were explicable by the single factor of stasis within the radicles of the hepatic veins. When one found enlargement of the liver which could not be accounted for on the basis of hepatic or interstitial disease it might be well to pay attention to the hepatic veins as they might afford the explanation of a number of cases of supposed cirrhosis.

Sir HUMPHRY DAVY ROLLESTON of London said he had studied this subject and that there were only about 30 cases reported in the literature aside from the case reported by Dr. Hoover. There might be an acute thrombosis such as described in Dr. Hoover's case or the process might be a slow one with dense cicatricial contraction of the orifices of the veins. He cited one case occurring in a child two years of age. In some the condition was a syndrome rather than a disease. The condition was associated with narrowing of the vena cava. Dr. Turner and Theodore Thompson thought that it might be due to trauma, to a certain amount of tearing at the point where the liver was attached to the vena cava, as the result of a fall or jar, and as a result a gradual cicatrization of the vessel walls took place. It was remarkable that Dr. Hoover had succeeded in making the diagnosis of the conditions for he felt convinced that it never had been diagnosed before.

Dr. FRANK WYNNE of Indianapolis related a case of phlebitis occurring in a young adult which, after several acute attacks and remissions, finally came to autopsy which showed extreme thrombosis and phlebitis of the portal vein.

Dr. HOOVER, in closing, said it was surprising to note for how many years a man with complete obstruction of the vena cava below the opening of the portal vein could go along without symptoms or with but transient symptoms. Some cases would have acute attacks and there would be a reopening of the lumen of the vessel or an anastomosis might be established which gave relief. Other cases gave symptoms lasting only a few hours.

Phlebectasis of the Diaphragmatic Area and of the Lower Thoracic and Upper Abdominal Regions.—Dr. WILLIAM GERRY MORGAN of Washington, D. C., read this paper in which he stated that in the routine examination of patients during the past twenty years he had noted occasionally an individual with marked dilatation of the cutaneous veins of the diaphragmatic area, chest and upper abdomen, and occasionally of the splenic area as well. There was an important pathological significance attached to this condition denoting some serious interference in the deeper circulation of the thoracic or abdominal cavities. In all except a few cases the author had found it associated with grave pathological changes in the body. An analysis of 100 cases taken from over 5,000 patients brought out certain interesting facts. This dilatation of the superficial capillaries over the diaphragmatic area was found almost exclusively in males over thirty years of age. It was found most frequently associated with the following conditions: disturbed arterial tension, syphilis, heart disease, aortitis, diseases of the gallbladder and liver, organic diseases of the nervous system, oral infection and severe constipation. Of the 100 cases, 95 per cent. were males and 5 per cent. females. The ages of the patients ranged from 24 to 82 years. The past history was negative in nearly all the cases.

Dr. J. RUSSELL VERBRYCKE, JR., of Washington, D. C., said they had probably all noted these marked capillary enlargements; he had observed them but had paid little attention to them and thought them accidental until Dr. Morgan had aroused his interest in them, when he began to observe them more carefully. He found the condition, as the writer had stated, almost exclusively in males of middle life. The distribution seemed to appear most commonly over the liver and next in frequency over the spleen or over both. There was not enough enlargement of the capillaries to indicate gross obstruction. The condition seemed somewhat analogous to acne rosacea and it had occurred to him that possibly the same cause was operative in both conditions. No one factor was found so frequently associated with the condition as to be considered the cause.

Dr. HOOVER called attention to a description of the condition published by Bismarck's physician in the late eighties. The condition seemed to have no relation to any known disturbance in the tributaries of the vena cava or portal system.

Dr. GENELLA said an Italian physician had described the condition and claimed that these abdominal varicosities were all a slow form of malignancy.

Dr. FRANK BILLINGS of Chicago recalled that twenty years ago Sir William Osler had visited a clinic in Chicago where a case of this kind was shown. He said he had been interested in the condition and had noted it frequently in children, and that it was characteristic of the tissues of some people. The condition was apparently not due to obstruction of the vena cava. It was found so often in children and young people without evidence of associated disease that he felt it might be assumed to be an abnormality of the individual.

Dr. WILLIAM S. THAYER asked Dr. Morgan if he had ever seen these enlarged venules running up on the chest. He had seen one case in which they extended up to the clavicle.

Dr. MORGAN stated that he had studied five or six thousand cases and had never seen the condition in a person under thirty years of age. He had seen only

one case in which the dilated venules extended up over the chest on the left side and this patient had a widespread thickening of the lung on that side.

Second Day—Thursday, April 29.

Change in Type of Disease.—Sir Humphry Davy Rolleston of London delivered this address, in which he discussed from various angles the question of the change in type of clinical disease. He stated that his subject was an old one, and quoted liberally from Sydenham to show the views formerly held on this subject. Many had held that the idea that types of disease had undergone a change was not proven and that the supposed changes were rather in the mind of the physician than in the condition or symptoms exhibited by the patient. Clifford Albutt, on the other hand, long ago said that disease was not a fixed entity. In considering this question certain facts stood out plainly. Scarlet fever, though perhaps not less frequent, was less fatal than formerly. Pneumonia had certainly undergone an increase in virulence. The type of the disease called influenza had certainly changed since 1889. On this point of change in type in influenza the British had some statistics which though small were striking. There were two waves of influenza in 1918. In the first wave but 4 per cent. of the cases in the navy had complications and the mortality was 1.03 per cent. During the second wave, occurring in October, 1918, the incidence of complications was 7 per cent. and the mortality 3 per cent. It must be admitted that this was a rather remarkable difference, and that it went to show that at least in this instance disease was not a fixed entity. Alterations in clinical features usually regarded as typical might be due to several causes: (1) to differences in the virulence of the bacteria, and (2) to changes as regarded the resistance of the patient. It seemed reasonable that a highly virulent bacteria in a patient with low resistance might produce a fulminating type of disease, whereas an attenuated virus in the same patient or in an individual with good resistance might produce a very mild type of the disease or have no effect at all. The question was whether bacteriological changes and the changes in the resistance of the individual changed the type of disease or whether some mysterious factor was responsible which we did not know about. Bacteria, we knew, might vary as the result of external influences. Temperature, concentration of carriers and of hosts, and conditions of passage might influence the virulence and vitality of organisms. There was evidence that there were cycles of activity for certain bacteria; there were cycles of activity followed by periods of rest. Certainly secondary infection was a powerful factor in changing the type of disease. This was well illustrated by the difference in influenza during the first wave and later when there were secondary invasions by the streptococcus hemolyticus and the pneumococcus. Then there was also the question of different strains of the same organism. It had been suggested that cerebrospinal fever, acute poliomyelitis, encephalitis, and influenza were variants of the same morbid process. We had learned that what we formerly recognized as typhoid fever had at times been paratyphoid and that the paratyphoid might be either paratyphoid A or B. Likewise we had learned that there were different types of pneumococci and that the difference in the type of the organism explained the difference in clinical manifestation that we observed. Furthermore certain organisms seemed capable of modification so that they had what might be termed an epidemic constitution. Prophylactic vaccination in smallpox and antitoxin inoculation in diphtheria may have had an influence in diminishing the virulence of epidemics of these diseases. War nephritis, the essayist believed, was not a distinct entity but only an acute nephritis occurring upon a large scale among young men previously healthy. Many difficulties arose when one came to consider the changes in resistance of individuals at different times and changes in resistance of the race. Changes in manner of living from primitive conditions to those of modern civilization might have had a very definite effect in altering racial resistance. Then again there seemed to be such a thing as acquired racial immunity. As illustrating this, Sir Humphry cited instances of epidemics of measles among people in the South Sea Islands where measles before the outbreak of these epidemics was unknown. Epidemics of that kind had been characterized by an exceedingly high mortality, making it seem that there was such a thing as a certain amount of acquired racial immunity to measles. The same was thought to be true of syphilis, this disease being by no means as virulent as it formerly was. Certain specific organisms might give rise to clinical symptoms of widely different character. As instances of this, influenza might produce the symptoms of common cold; pneumonia, meningitis or enteric fever.

Abscess of the Lung.—Dr. U. J. W. Peters of Birmingham, Ala., presented this paper which was illustrated by lantern slides. He stated that a few years ago abscess of the lung was considered a relatively rare condition, but during the past few years an increasing number of cases were being reported. Abscess of the lung occurred most frequently after pneumonia or tonsillectomy or because of the presence of a foreign body in the lungs. When it occurred following tonsillectomy it was supposed to be due to the inhalation of septic material from the tonsils during or following operation. Abscess of the lung might be accompanied with little or no temperature, though occasionally there was a considerable rise in temperature. Frequently there was expectoration of large quantities of purulent fluid, more or less pain, and frequently hemorrhage. Leucocytosis was the rule though it was not always present. The *x*-ray was of great assistance in the diagnosis of abscess of the lung, and stereoptic examination was even more valuable. There were times, however, when the *x*-ray plates were rather confusing. The treatment was resection of the rib under local anesthesia, or if not under local anesthesia then gas oxygen was the second choice. Sometimes a fistula remained which did well if treated with bismuth paste. Clubbing of the fingers was almost uniformly present in cases of lung abcess.

Dr. Charles H. Hoover of Cleveland, Ohio, called attention to the fact that nothing was said in the paper about auscultation in the diagnosis of lung abscess. Frequently when nothing could be heard with the stethoscope the ear applied directly to the chest would be able to detect a rather loud bronchial respiration. Another point of importance was anoxemia, which was helpful in making the diagnosis between intrapulmonic abscess and an abscess between the lung and the chest wall.

Dr. Oscar M. Gilbert of Boulder, Col., spoke of the need of differentiating bronchiectasis from lung abscess; this was important because in bronchiectasis surgery was not successful. Another point was the production of slight adhesions to the chest wall by means of artificial pneumothorax. He had first attempted the production of artificial pneumothorax in a case of chronic lung abscess with extensive infiltration throughout the affected lobe of the lung and found this very successful in limiting the process so that a surgical operation could be more easily performed. Following this experience he had made use of artificial pneumothorax in other cases and found that following artificial pneumothorax surgery was easier.

Dr. Allan Custis of New Orleans called attention to a type of lung abscess that came to their clinic which followed amebic abscess of the liver when such an abscess pointed up and ruptured through a bronchus. When this occurred bronchophony and pectoriloquy would be found low down in the chest. In making the examination, it was well to bear this in mind and to listen over the lower right chest.

Oxycephaly: Its Occurrence in Negroes.—Dr. George Dock of St. Louis made this presentation which was illustrated by lantern slides. He said that owing to the relation of oxycephaly to exophthalmos most of the descriptions of the condition were confined to ophthalmic literature. These cases were usually seen first by the pediatrician or the ophthalmologist. Other names had been applied to the condition, such as tower skull hypsicephalia. Osler had used the term ocycephaly, and he thought this most appropriate, as the condition was due to a cranial defect associated with impairment of vision. It was supposed to be caused by the premature closure of the sagittal, coronal, and lambdoid sutures. Not only were there changes in the upper part of the cranium but in the base of the skull as well.

The defects occurring in the shape of the skull varied enormously and affected the shape of the orbits of the eyes as, for instance, when the vertical axis of the skull was too high the orbits were high and narrow. These deformities had been attributed to rickets, to syphilis, and to endocrine disturbance, but the true etiology remained unknown. The pathology was that of premature closure of the sutures. The symptoms varied in different individuals and at different times in the same individual. Among the most common symptoms were papillitis, choked disc, and exophthalmos. If the children were not born with this condition it was usually observed from the third to the tenth year of life, when eye symptoms manifested themselves. Exophthalmos occurred in about one-half of the cases, while in others such conditions as keratitis, papillitis and choked disc were noted. The exophthalmos occurred in those cases having changes in the base of the skull, as when the wings of the sphenoid were too short and too oblique. The diagnosis depended chiefly on the skiagram of the skull and especially upon the stereoscopic skiagram. All the landmarks of the skull were likely to be altered and all sorts of deformities occurred. It was important to detect the condition as early as possible by the finding of convolutional atrophy which was supposed to be the result of increased intracranial pressure, though the true cause of the atrophy was not readily understood. In order to find if there was increased fluid recourse must be had to surgery. The simplest operation was lumbar puncture, but this should be used very carefully, as there was danger that a portion of the cerebellum might be sucked into the spinal canal. Ventricular puncture was to be preferred. One point to be brought out was that exophthalmos in negroes was not always due to endocrine disturbance since oxycephaly was very frequent in the negro race, and some of these cases of oxycephaly had tachycardia.

Dr. STEWART ROBERTS of Atlanta, Ga., declared that it was not generally recognized that there was a great deal of pathology in the full-blooded American negro. Another name applied to this condition was acrocephaly, which was probably more description than oxycephaly. There was unquestionably in the Southern negro a natural exophthalmos, and he had also been impressed with the frequency of exophthalmic goiter in the full-blooded negro. He thought, however, that this natural exophthalmos had been overlooked. These people with natural exophthalmos often complained of headache and visual disturbances. Mothers frequently brought children who were inactive, listless and rather thinner than they should be, who were apparently suffering from this condition. So far as he had observed, this condition interfered in no way with whatever Ethiopian intellect was present. Often children having this condition were supposed to be suffering from the effects of enlarged tonsils or adenoids, and the possibility of acrocephaly overlooked.

Clinical Experience with a Standardized Dried Aqueous Extract of Digitalis.—Dr. JOSEPH H. PRATT and HOWARD F. WEST of Boston made this contribution which was presented by Dr. West. He described the preparation of a dried aqueous extract of digitalis, in which the active principles of digitalis were in more concentrated form than they occurred in the leaf, and which was made to conform to the U. S. P. standard by mixing with lactose. A freshly prepared infusion was evaporated to dryness. This gave a fine brown powder which had maintained its activity for a year. Each lot was assayed and mixed with equal parts of anhydrous sodium sulphate, which aided in protecting the powder from moisture. It was put up in capsules containing 5.5 frog units each. The digitalis was grown in Virginia and Oregon. This preparation had been used in a considerable number of cases in the Peter Bent Brigham Hospital with uniformly satisfactory results. It was found that 39 mg. of standard leaf per kilo body weight, discounting edema, was the average physiological dose. When given rapidly, largely as single doses, to patients with auricular fibrillation, an initial effect as judged by the slowing of the heart rate was noted in from three to six hours—a complete effect in from twelve to twenty-four hours. Marked diuresis was frequently seen after large doses. When used in patients with regular rhythm who had obvious symptoms of heart failure the effects were quite satisfactory as in those with auricular fibrillation. After large single doses they showed rapid clinical improvement, and the vital capacity of the lungs showed prompt and striking increases, amounting to as much as 15 to 20 per cent. in twenty-four hours. The vital capacity offered a valuable measure of improvement, and in patients with regular hearts was the best graphic indication of the therapeutic effect of the drug, since there was usually much less change of the heart rate than in patients with auricular fibrillation. The physiological dose was found to be practically identical with that found by Eggleston, that was, 0.145 cat units per pound body weight when the patient had become free of edema. Careful observations were made showing the effect of this preparation on pulse rate, urine output, weight, and vital capacity.

Dr. CANBY ROBINSON of St. Louis said that recent advances in our knowledge of the action of digitalis might be spoken of under three heads: (1) They had learned to use sufficient quantities of digitalis; it might be used in quantities sufficient to get therapeutic results or even early toxic symptoms; (2) they had learned to recognize the early toxic symptoms by the use of the electrocardiagram, the estimation of the vital capacity, and by toxic symptoms, such as nausea and vomiting; (3) they had learned the importance of a standardized preparation of digitalis. They were therefore in a better position to treat heart disease than they previously were and they had learned to differentiate their cases better than they formerly did. They knew that digitalis was valuable in cases of great irregularity of the heart, but where the heart was regular digitalis did not produce such striking effects. He was glad Dr. West had told them of the effects of digitalis on hearts beating normally and on the normal vital capacity. Peabody had shown that the vital capacity bore a constant relation to the state of the circulation and diminished as the circulation became deficient. The aqueous extract was valuable in that it could be standardized and it was a definite help to have a drug that would act rapidly.

Dr. C. F. WAHRER of Fort Madison, Iowa, deplored the fact that the general practitioner was at the mercy of the commercial houses when it came to procuring digitalis and condemned the many worthless preparations on the market. The general practitioner was at a disadvantage as he did not have at his disposal the laboratory facilities to make a reliable preparation of digitalis such as Dr. West had been able to make. He had heard Sir James Mackenzie say that he had the same trouble in getting a reliable preparation of digitalis. It was most unfortunate that the bulk of practitioners had to depend upon therapeutic houses for the digitalis they prescribed.

The Study of Bile Pigments in Pernicious Anemia.—Dr. JOHN P. SCHNEIDER of Minneapolis, Minn., read this paper, in which he reviewed his work on the quantitative estimation of bilirubin, urobilin, and urobiligen as determined by a duodenal method of estimating hemolysis with the aid of the spectroscope, which was published in 1916. In securing the duodenal contents the Einhorn duodenal tube was used, and one might be sure that he had obtained duodenal contents when the reaction was alkaline to litmus and there was no free hydrochloric acid. This method was simple, reliable, and reasonably accurate. The stool method was subject to certain errors. Of prime importance was the fact that urobiligen was never found in health. In pernicious anemia the finding of urobiligen was so uniformly in accord with the clinical symptoms that it was a most valuable diagnostic aid. In 84 per cent. of 100 cases of pernicious anemia studied, the bile pigments were far above normal and showed a constant increase proportional to the severity of the anemia. Observations were made on normal individuals placed successively on carbohydrate, milk, mixed, and high protein diet for three or four days prior to the examination of the duodenal contents. It was found that the total bile pigments in normal individuals never exceeded 1000 units and usually ranged between 400 and 800 units. The effect of purging, constipation, and quinine sulphate or the value of bile pigments was also studied. In this series of observations urobiligen occurred only once and that was in a case of lacunar

tonsillitis. Quinine sulphate in large doses produced an increase in bile pigments, which remained high for as long as thirteen days after the administration of the drug, this probably being due to the hemolytic effect of quinine. It was noted particularly that high values for bile pigment were associated with ringing of the ears produced by quinine. Studies were being made to determine whether quinine acted directly upon the red blood cells or upon the parenchyma of the liver and spleen. In the series of cases of pernicious anemia the average total of bile pigments was 3,330 units, the highest being 6,800 and the lowest 800. This test was of great value in the diagnosis of pernicious anemia when the blood or clinical picture was not decisive.

Dr. L. G. ROWNTREE of Minneapolis said he had been interested in this subject ever since Wilbur and Addis published their work with reference to the estimation of bile pigments. He had seen these cases of pernicious anemia that Dr. Schneider described and they had shown constantly high values of bile pigment, so that one could not help being convinced of the value of this test. He felt that the method of estimating bile pigments as described by Dr. Schneider should receive much more attention than was being given to it. He discussed the effect of quinine on hemolysis and suggested a possible relationship between quinine and the hemolysis seen in blackwater fever.

Dr. SCHNEIDER, in closing the discussion, said there was constantly an excess of bile pigments in icterus and in a variety of infections. In an examination of 4,800 miscellaneous cases there was an excess of bile pigments in 1,600, but the highest values were obtained in pernicious anemia.

Spondylitis and Abdominal Pain.—Dr. DOUGLAS VANDERHOOF of Richmond, Va., read this paper, in which he said that spondylitis, familiar to the orthopedist, was not generally recognized by the internist and surgeon. Involvement of nerve roots in arthritis of the spine might give rise to referred pains, not only in the shoulders, hips, and extremities, but also in the chest and abdomen. Symptoms referred to the abdomen might simulate visceral disease and might vary from vague discomfort to paroxysms of acute pain. In a series of 87 cases of spondylitis observed by the writer, abdominal pain occurred in 23 patients in whom visceral disease could apparently be excluded. Errors in diagnosis led to needless operations on the gallbladder and urinary tract. Spondylitis with referred pain was much more frequent than tabetic crises. Relief of the nerve root pain was secured by proper orthopedic treatment with removal of responsible foci of infection. Four illustrative cases were cited.

Dr. WILLIAM S. THAYER of Baltimore confirmed what Dr. Vanderhoof said regarding the possibility of making an incorrect diagnosis in spondylitis on the basis of referred pain. There were instances of hypertrophic arthritis of the spine which produced symptoms such as had been described and which might be confused with abdominal disturbances; that fact needed emphasis. Another condition which affected the posterior root ganglia and sometimes gave symptoms resembling those of renal calculi was herpes zoster.

The Influence of Quantitative Methods in the Advance of Clinical Medicine.—Dr. EUGENE S. KILGORE of San Francisco, Cal., made this presentation, in which he emphasized the fact that medicine following the precedent of other sciences was seeking to advance through the use of quantitative methods of research. The ordinary medical writer tried to present his observations in tabular or graphic form. This undertaking involved much more than the mere presentation of figures. The multiplicity of variables inherent in laboratory and clinical material required statistical methods of analysis and interpretation. Medical writers generally had relied purely on intuition in their interpretation of figures. This practice led very frequently to gross misstatements of results and had thereby brought unmerited discredit on statistical methods. The elementary theory of probabilities, almost never employed by medical writers—dealt scientifically with these methods, was a comparatively simple branch of mathematics, and should be required in the premedical curriculum. A portion of the time devoted to higher algebra, trigonometry, and conic sections might better be applied to the study of statistical methods which would afford just as much mental training and would be of practical value to the student in his daily work.

Dr. HENRY A. CHRISTIAN of Boston said it was undoubtedly true that there was a false security in figures and that nothing lied like statistics. If with insufficient knowledge one attempted to utilize figures he would make mistakes. One very common error was that of drawing conclusions from a small group of cases where there were all sorts of chances of error. Another common error was to figure our percentages on some symptoms or finding; for instance, if one found 30 per cent. of patients having a certain condition to have bad teeth he might conclude that bad teeth were the cause of that condition, without stopping to get the figures as to how often bad teeth were found in individuals who were well, or how often bad teeth might be found in patients with an entirely different disease. There was also another class of error. The statistician might fall into the error of assuming that he was dealing with accurately collected data, whereas the data upon which statistics were based might be inaccurate. For instance, the relative number of deaths due to influenza and to influenza complicated by pneumonia. During the epidemic physicians were often so busy that they did not know definitely whether a patient did or did not have pneumonia. Frequently there were very few signs of pneumonia in these cases, and yet when they came to autopsy extensive pneumonia would be found. There were errors that occurred when statisticians juggled accurately with data that was inaccurate. The medical man should take all these things into account before he got into a statistical discussion.

Dr. KILGORE, in closing the discussion, said the important point he wished to leave with his hearers was that those interested in education should see that the next generation was qualified to use statistical methods in their work.

Frozen Sections from Two Cases of Aneurysm of the Thoracic Aorta.—Drs. GEORGE W. NORRIS and GEORGE FETTEROLF of Philadelphia gave this presentation, which consisted of a lantern slide demonstration of the findings in two cases of thoracic aneurysm. The bodies were injected with formalin, frozen, and then cut in serial sections. These sections demonstrated the size, position, shape, and anatomical relations of the aneurysm as seen from different points of view. The site of the rupture was clearly demonstrated, being in the left bronchus in one case and into the trachea in the other. Pulmonary complications, such as pleural adhesions, pleural effusion, etc., were also demonstrated.

Third Day, Friday, April 30.

Gout: A Clinical Study of 116 Cases.—Dr. CHARLES SPENCER WILLIAMSON presented this paper in which he analyzed this series of cases of gout collected in two large charity hospitals in Chicago. He said the first striking fact brought out by this study was that gout was much more frequent in this country than was usually supposed. It was probably the type of joint lesion most frequently unrecognized, whether in acute or chronic form. The cases were analyzed in reference to incidence by age decades and race. A study of the influence of lead and alcohol as etiological factors yielded no evidence that lead had any relation to gout. Alcohol, on the other hand, seemed to have an exceedingly striking relation to the disease, most of the patients being heavy drinkers. It seemed to make no difference whether the alcohol consumed was in the form of whiskey or beer. Traumatism did not seem to be an element in the etiology. Of 101 cases studied with reference to nutrition, 92 were found to be well nourished. Of the 116 cases, 45 per cent. showed albuminuria, and a queer thing was that in spite of the presence of albuminaria there was relatively little nephritis. The onset was usually characterized by pain in a joint, intense, and sometimes agonizing; the joint became swollen, red and hot. A remarkable feature in connection with attacks of gout was the similarity of symptoms in the first and subsequent attacks. There was usually an interval of some years between the first and subsequent attacks, the average interval being ten years. The average age incidence was forty-eight years. The great toe was involved more often than any

other joint in first attacks, and if not involved in the first attack it usually became involved later. In 95 per cent. of cases of gout the great toe became involved sooner or later. When the first attack came on in the day time, as a rule subsequent attcks occurred in the day time, and if the first attack came on at night, so did subsequent attacks. Most cases that began as a monoarthritis later became polyarthritic. It was remarkable how little elevation of temperature occurred and how slight were the clinical symptoms even when half a dozen joints were involved. Even in the most skilful hands the *x*-ray was of little value in the early diagnosis of gout, and not only was it of little help but it might be actually misleading. In the later stages the condition was easily recognized without the help of the *x*-ray. Severe sore-throat preceded the first attack in five instances. The point particularly to be stressed was that gout was much more frequent than had been supposed and that there was often a failure to make the diagnosis because of its supposed rarity.

Dr. WALTER L. BIERRING of Des Moines, Iowa,said that when one considered that these cases came from two large charity hospitals it did not seem at first glance that they demonstrated such a very large increase in the incidence of the disease, but when one took into consideration the better nutrition of people elsewhere in comparison with that in the poorer sections of a large city it would seem that there not only was an increase in the incidence of the disease but that there was some other factor besides nutrition at work in the large cities. The frequency with which alcohol had been used by those who came to the clinics in the city was at least suggestive. The symptoms of gout were so well marked that it was rather striking that the disease should be overlooked. He thought this was because attention had been so centered on the various forms of arthritis in relation to focal infection that gout as a possible cause of joint affection was likely to be overlooked. He thought the *x*-ray of considerable importance in the early diagnosis of gout in a negative way, because of the fact that early in the course of the disease no definite bone or joint changes were shown. The most reliable point in the diagnosis of gout was the existence of tophi; when these were present there was no doubt as to the existence of gout.

Dr. ALEXANDER LAMBERT of New York stated that gout was not infrequent in New York. Among those of English and Irish ancestry it seemed to be more frequent than among others; but this might not be a safe conclusion. There were often other idiosyncrasies of gouty people, which might run differently in the same family. He knew of one family in which one brother could not touch red wine, while another could not touch white wine, and still another member of the family could not touch alcohol at all. Food idiosyncrasies also had much to do with it. One point of diagnostic significance was that in a gouty joint the maximal point of tenderness was almost invariably on the side. As to the etiology, the dry skin, dry hair, dry, chipping nails and sometimes other evidences of hypothyroidism together with the fact that iodine was one of the best remedies in gout and that it also stimulated thyroid activity was suggestive. Dr. Lambert said that while recognizing the dangers of the *post hoc propter hoc* conclusion, he was inclined to think that the thyroid had a great deal more to do with gout than we had hitherto supposed. A few cases treated on the basis of a lack of thyroid had responded more satisfactorily than when treated in other ways.

Dr. WILLIAMSON, in closing the discussion, recalled that Garrett had said that in any arthritis involving the great toe one should be suspicious of gout. He thought the fact of the great acuity of local symptoms together with the very slight fever was an important diagnostic point in reference to gout which had not worked itself into the consciousness of the average physician. The fact that attention had been centered on focal infection had perhaps been responsible for some of the failures to recognize gout. Dr. Williamson cited cases treated as arthritis, as fracture of the metacarpal bones, etc., when there were tophi in the ears, and tophi came only after the disease had been present for years and were of no help in the early diagnosis. He was glad to hear Dr. Lambert say the pain was on the side of the great toe, for so far as he knew that was true, but he had not had the courage to take that into consideration in making the diagnosis. The point brought out in regard to the thyroid was very suggestive. Gout was a common disease in America, a fact not generally recognized, while it had been overestimated in England.

Renal Glycosuria.—Dr. JAMES E. PAULLIN of Atlanta, Ga., read this paper and reported a case with studies to determine effects of various diets on the sugar content of blood and urine. He states that his object was to call attention to a condition of renal glycosuria in which the sugar content of the blood was normal and the tissues were utilizing a normal amount of carbohydrate, and yet there was a constant glycosuria very slightly influenced by diet and the usual symptoms of diabetes mellitus were absent. This condition was not common, but some patients were treated as mild diabetics who had renal glycosuria. Simple methods for the estimation of blood sugar would be helpful in the study of this group. He had found three cases of renal glycosuria among forty cases of supposed diabetes mellitus. These cases, however, were usually discovered in the course of routine physical examination or in patients rejected for life insurance because of sugar in the urine. Dr. Paullin cited in detail the case of a young man, 23 years of age, who was first seen in August, 1915. His family history was negative and his past history uninteresting except that he had had typhoid fever and recovered completely without complications, and at the age of 18 a mild attack of measles, also without complications. His general health had always been excellent and he had always been interested in athletic sports. His diet had never been restricted, and he gave no history of polyuria or other symptoms of diabetes. His lungs and heart were normal; his blood pressure was 120 systolic and 80 diastolic. The blood count was normal and the Wassermann reaction negative. The urine showed a specific gravity of 1023; a marked trace of albumin; heavy sugar; no acetic or diacetic acid. On further investigation it was thought that this was a case of orthostatic albuminuria. The phthalein test gave 65 per cent. A number of examinations were made over months and all showed sugar varying from 0.5 to 2.1 which was the highest ever found. He was tried on various diets, carbohydrate and protein, but was never sugar-free even on very restricted diet, and in fact there was almost as much sugar on the low diet as on the unrestricted diet.. They were finally convinced that this was not a case of true diabetes but one of renal glycosuria. Now, after three years, the glycosuria was no greater, possibly less, than when he was first seen, and he was in excellent health. Sugar tolerance tests gave practically normal results. Too few cases had been observed to say that these individuals did not develop true diabetes later on, although it would seem that the existence of such a condition was not incompatible with normal existence. There had been no progress toward diabetes in this case.

Dr. NELSON W. JANNEY of Santa Barbara, Cal., called attention to the fact that it was in just such cases as this that the glucose tolerance test was of the greatest value. He had on record a number of similar cases in which a perfectly normal curve for glucose tolerance was found. It seemed as if in typical cases of renal glycosuria we should expect a fairly normal blood tolerance glucose curve, but one must not be deceived by the blood sugar or the sugar tolerance curve for there were typical cases of diabetes that gave a fairly normal glucose tolerance test. Cases in which the blood sugar tolerance tests have high values were unquestionably true diabetes, even though they did not give definite symptoms of diabetes.

Dr. ALLAN EUSTIS of New Orleans pointed out that in cases in which there was liver disturbance or in cases of intestinal toxemia the urine might reduce Fehling's solution, but it did not ferment or react to polarized light. In those cases of intestinal toxemia in which these reducing substances were found in the urine, if the toxemia was overcome the reducing substances would disappear from the urine. He had a patient under treatment for chronic gallbladder trouble and deficiency of liver function on a low protein diet whose urine showed these reducing substances. This patient had gained twelve pounds in two weeks on the

low protein diet. He thought this question of the presence of reducing substances in cases not truly renal should be studied. If there was poor liver function the giving of coffee would produce a substance in the urine which would reduce Fehling's and he wondered if this was the effect of the caffeine.

The Treatment of Diabetes Complicated by Pulmonary Tuberculosis.—Dr. NELSON W. JANNEY of Santa Barbara and Dr. ROBERT R. NEWELL of San Francisco made this presentation which was read by Dr. Janney. He stated that the treatment of diabetes complicated by tuberculosis presented great difficulties, inasmuch as diabetes was treated by undernutrition and exercise while pulmonary tuberculosis was treated by hypernutrition and rest. A representative series of cases of diabetes complicated by tuberculosis was accordingly studied with the object of determining what modifications of modern methods of treatment were advisable when these two diseases occurred together. It was interesting that Montgomery, in reviewing 31,834 cases, failed to find a single active case of tuberculosis that developed diabetes, while pulmonary tuberculosis developed quite frequently in diabetes. All the statistics indicated that it developed in 15 to 25 per cent. of the cases. Dr. Joselin reported that 3 per cent. of his diabetic patients developed tuberculosis before the use of the Allen method, but that this percentage had been reduced since using the Allen treatment. It was noted that at autopsy tuberculosis was found much oftener than it was recognized during life by the physician. With regard to the symptoms of tuberculosis complicating diabetes, they were very insidious. The emaciation frequently shown by the patient was attributed to the diabetes in many instances so that the tuberculosis made considerable progress before it was recognized. There were the usual symptoms of tuberculosis, fever, and hemoptysis, and the lesions were much more extensive than in uncomplicated tuberculosis. The prognosis was that of either disease made worse by association with the other. Prognosis also depended upon treatment which was particularly difficult to carry out, inasmuch as the tuberculosis sanitarium was not fitted with the laboratory facilities and diet kitchen necessary for the proper treatment of the diabetic and the care of the tuberculosis patient was certainly not in keeping with the plans of the diabetic clinic to say nothing of the danger of exposing other diabetics to infection by tuberculosis. We had not at present an ideal place for the handling of this combination of diseases. Dr. Janney reported in detail data concerning 16 cases of diabetes complicated by tuberculosis, two of whom died of diabetes while five succumbed to tuberculosis. With regard to the question whether it was permissible to permit a patient having diabetes complicated by tuberculosis to exhibit glycosuria, Dr. Janney said they had found that the large majority of these cases had developed tuberculosis when on a high diet. Only five developed diabetes when sugar-free, and only one of these was taking less than 30 calories per kilo. Lowered resistance due to upset metabolism was an etiological factor in the development of tuberculosis in diabetics. In connection with the question of undernutrition as an etiological factor in the tuberculosis of diabetics, it might be observed that in other wasting diseases, such as leucemia, exophthalmic goiter, Graves' disease, etc., tuberculosis developed with comparative rarity. It seemed that undernutrition was not as much a factor in the development of tuberculosis as lack of treatment of the diabetes. Undernutrition sufficient to control the diabetes was justifiable. Before using the Allen treatment 1.7 per cent. of Joselin's cases died of tuberculosis; since adopting the Allen treatment only one case died of pulmonary tuberculosis out of 748 cases of diabetes. Control of the diabetes might be followed by immediate improvement of the tuberculous process. Fasting was unnecessary to obtain good results. Rest was at least as necessary as in the treatment of uncomplicated tuberculosis. Every patient was kept in bed until it could be shown that the effect of undernutrition was not injuring him, for there was distinct danger of carrying the undernutrition too far. Practically all the cases in this series became sugar-free in three days, and in all cases the acidosis disappeared. Twelve of these sixteen patients showed definite improvement under institutional treatment. In the treatment of the diabetic whose case was complicated by tuberculosis the greatest discretion was imperative, and his proper treatment was difficult to carry out in the home.

Dr. FRANCIS M. POTTENGER of Monrovia, Cal., congratulated Dr. Janney on his paper, which he said showed, first, that you must not allow the diabetic to develop tuberculosis and, secondly, that if he did develop tuberculosis his tuberculosis must be cared for in its early stage otherwise there was little help for him. It was natural in true diabetes that tuberculosis should develop, owing to the undernutrition and lowered resistance of the patient. Recognizing that quiescent tuberculosis was present in many people, one could readily see why its effect would be greatly increased in diabetes, and it was not surprising that a larger number of untreated diabetics developed tuberculosis than of those treated. He believed that if the diabetic were treated and kept in good condition a very small percentage would develop tuberculosis, or if tuberculosis did develop and was immediately treated many patients would recover. The treatment was a particularly serious problem, hence prevention was better than cure. We must adhere to rest in tuberculosis and particularly if it was complicated by diabetes. The question of recovery in tuberculosis was one of saving the patient's resisting powers. Since emphasizing rest in the treatment of tuberculosis they were getting much better results than before this was done. Lying in bed, the patient lived with the least possible expenditure of energy. It required two or three times as much energy if the individual was up and about. If the tuberculosis was active the toxemia became greater and the diabetes became worse. If there was an acute type of tuberculosis the diabetes progressed rapidly unless it was helped.

Dr. FREDERICK M. ALLEN of New York said that coma was the most frequent cause of death in diabetes; tuberculosis ranked second in frequency as a cause of death, and gangrene came third. Coma could almost always be prevented, gangrene could always be prevented, and likwise other complications. He had never seen a complication develop in a diabetic perfectly treated. Dr. Allen said he could not disagree in any way from the reader of the paper. Fasting might be avoided in some cases, but the tuberculosis diabetic should be fasted as long as was necessary. It was seldom that the untreated diabetic with tuberculosis lived over six months. The tuberculosis was a secondary infection and advanced rapidly. It was striking, however, to see how rapidly a secondary infection did improve as a result of the treatment of the diabetic condition. But we should not be either too optimistic or too pessimistic, for if either disease was severe the prognosis was absolutely hopeless. In the milder cases a great deal more could be accomplished. That meant they should not be entirely pessimistic. The goal that could be reached was the prolongation of life from several months to several years with comfort and usefulness by means of a careful diet. It was pitiful to see these patients wasting away with a combination of tuberculosis and diabetes, but the tuberculosis progressed more rapidly if the diet was unrestricted. Dr. Allen emphasized what Dr. Janney had said with reference to the impossibility of treating the diabetic with tuberculosis satisfactorily either in a metabolic clinic or a tuberculosis sanitarium. He pointed out that in the series of cases reported, Dr. Janney had had the advantages of climate and constant supervision of his patients under the most favorable surroundings. There was great need of an institution properly equipped to care for this particular class of patients. Diabetics treated thoroughly from the start seldom developed coma, gangrene, or tuberculosis.

Dr. ROBERT R. NEWELL of San Francisco said that while the combination of tuberculosis with diabetes was becoming comparatively rare, they saw a considerable number of cases, and he was seldom without one or more patients of this class. Although the cure of the diabetes was the primary object, if this were carried out the tuberculosis benefited as well. Dr. Newell also urged the need of an institution for the treatment of this complication of diseases. It would be a wonderful thing if they could have an institution where patients could receive appropriate treatment for

diabetes and at the same time the rest required in the treatment of pulmonary tuberculosis; better results could then be obtained than were possible either in the metabolic clinic or the tuberculosis sanitarium.

Dr. L. T. GENELLA of New Orleans held that it was very easy to recognize tuberculosis in the diabetic because expectoration was usually very profuse so that there was an abundance for making a bacteriological examination.

Dr. JANNEY, in closing the discussion, did not agree that it was always an easy matter to recognize early tuberculosis in the diabetic. In many cases he had found that the sputum was not positive. The thing that had impressed him had been the failure to study these cases carefully. A special institution for their treatment was most important, not only for the patient with these conditions in acute form but in order to teach patients with these conditions diabetic cooking and all the things they should know in order to care for themselves properly if they had these diseases in a mild form, so that they could leave the institution prepared to carry out these measures so necessary for the prolongation of life. He felt that it was only fair to pay a tribute to Dr. Allen who had given them a method of treatment which was not only effectual in the treatment of diabetes but which was so helpful in the treatment of this combination of diseases.

Arterial Hypertension Associated with Endocrine Dyscrasia.—Dr. WILLIAM ENGELBACH of St. Louis made this contribution, in which he stated that the purpose of his paper was to furnish additional evidence to the recent literature which attempted to associate a certain selected group of cases having arterial tension with disturbances of the internal secretions. To do this it was first necessary to select cases with positive glandular disturbances and to exclude those with cardiorenal conditions which might be causing the hypertension. Five hundred cases with definite glandular disturbances were selected for this purpose in whom accurate blood pressure and all other determinations were made. Of this number 40 had systolic blood pressures over 160, and a surprisingly high number of endocrine cases treated for their glandular disorders were relieved of their hypertension. Some of these patients had lived for a number of years disregarding their high blood pressure. Dr. Engelbach said he had no intention in his paper to discount arterial hypertension from arteriosclerosis or renal lesions, and he wished to state that he believed the problem of hypertension was still unsolved. A great many theories had been advanced which propounded changes other than those in the arterial and cardiovascular systems. His thesis was that many cases heretofore described under such terms as the prealbuminuric stage of Bright's disease, latent arteriosclerosis, pre-arteriosclerotic hypertension, pure hypertension, benign hypertension, etc., had a relation to the ductless gland dyscrasias. Of these cases of hypertension the highest percentage was found among the polyglandular cases, 30 per cent. having been classified as having more than one gland involved. In 12 per cent. of these cases the pituitary and thyroid were differentiated as being most frequently associated with hypertension. A considerable number of cases of hypertension occurring at the menopause were due to glandular disturbance. Treatment was directed entirely to the glandular state, and to this treatment the great majority of these cases had responded.

Dr. FRANCIS M. POTTENGER of Monrovia, Cal., spoke on the subject of the physiology underlying hypertension. He said we had studied disease and we had studied the results of disease but we had neglected to study this bridge over which the cause operated to produce the effect. Every smooth muscle and every secreting gland had some nerve controlling it and all were influenced by the internal secretions. We had two ways through which stimuli operated and the results were seldom due to one thing. A symptom was the result of all the stimuli that were acting. If we found a slow pulse or a rapid pulse it was because something acted to make it slow or rapid. For example, ordinary tension, where there was not only constriction of the arteries but vaso-constriction and we knew that adrenalin acted upon the glands and blood vessels. Then, in addition, here were psychical stimuli and the psychical stimuli might disappear through the nervous system or the endocrine system, consequently a hypo- or a hyper-condition would simply be the result of all the factors which were acting.

Dr. GUSTAV ROUSSY of Paris, France, spoke of the relationship of arteriosclerosis to disorders of the adrenals and other internal glands. In order to investigate this relationship they had performed a great many autopsies to determine whether, after all, the adrenals were the primary element in clinical hypertension and arteriosclerosis. They had studied the glands of internal secretion in 200 cases of arteriosclerosis and hypertension. In many instances definite changes could be made out in the adrenals and particularly in the cortical area. Sometimes there were changes in the pituitary, particularly in chromaffin element, and an augmentation in the number of chromaffin bodies. There were changes in the thyroid and parathyroid in some instances. In other instances of well-marked arteriosclerosis, changes in the glands could not be made out. In studying this question one should study not only the anatomical condition but the interpretation of this condition. Lesions of the glands of internal secretion associated with arteriosclerosis might be interpreted in the sense that the arteriosclerosis was purely secondary or it might be that the converse was true, that the changes in the glands of internal secretion were secondary to the changes in the vessels, and possibly they might both depend upon some other condition which as yet we did not know. Dr. Roussy pointed out the importance in all instances of arteriosclerosis of studying the actual anatomical relations between the arteriosclerosis and the glands of internal secretion, since at the present moment the relationship was hypothetical.

Dr. FISHMAN said he thought that we had a right to say that the glands of internal secretion were affected where there was a high blood pressure and a high glycosuris for a glycosuria might be produced by adrenalin substance and adrenalin also produced clinical high blood pressure. These cases should be treated by a lack of carbohydrates until the glycosuria came down to normal. He believed from his observation in these cases that increase in adrenalism or increase in chromaffin secretion might be responsible for high blood pressure, and also for glycosuria.

Dr. FREDERICK M. ALLEN of New York said it must be remembered that was not a disturbance of the glandular system. It had been brought out very definitely that hypertension yielded to a salt-free diet. There were very few cases that would not yield to a diet that was absolutely salt-free; the difficulty was that the majority of patients did not get an absolutely salt-free diet. If such a diet was instituted it would be found that many supposed endocrine disorders would respond. Hypertension at the time of the menopause was of that type. Many elderly women who had hypertension improved on a salt-free diet. Also in diabetes there were a good many patients with hypertension and the hypertension would come down to normal when the glycosuria was controlled, though all did not come to normal.

Dr. W. S. THAYER of Baltimore reminded them that it was one thing to note an association and another thing to jump at a conclusion. The actual physiological cause of hypertension in most instances was by no means clear. We knew that a spasm of the peripheral vessels would cause hypertension, and there was fairly good evidence that thickening of the small peripheral vessels was followed by hypertension, and that was very nearly all we knew about hypertension except certain associations. Dr. Thayer said he would like to know what the figures were in reference to the results of treatment of hypertension that the writer believed were due to glandular disturbance and how long the cases had been observed. Dr. Allen had had most remarkable results with the salt-free diet, and he was interested in knowing how long Dr. Allen had followed the cases in which he had limited the salt; he also would like to know how they stood this diet for a long time.

Dr. ALLEN replied that the longest observation was fifteen months, and the results were permanent where results were obtained. The salt-free diet was borne differently by different individuals. If the chloride

threshold was high the sudden deprivation of salt would not be felt, but if the chloride threshold was low the patient became weak, the chloride might not be borne so well. It would be necessary to determine the normal chloride threshold and the salt ration for each individual patient.

Dr. ENGELBACH, in closing the discussion, said it must be admitted that there was no definite relationship established histologically or pathologically between these conditions. Dr. Fishman had spoken of the involvement of the adrenals; the point brought out in the paper was that there were very few cases in which one gland alone was involved. The majority of the cases were polyglandular. He felt sure Dr. Allen was right about the chlorides. They had the same results in some cases, yet other cases that did not receive the salt-free diet responded to endocrine treatment.

Syphilis of the Kidney.—Dr. LOYD THOMPSON of Hot Springs, Ark., presented this contribution in which he claimed that the importance of this subject had been often overlooked; even Osler had paid little attention to it. Cabot in his urology gave quite a complete description. Statistics were difficult to obtain though Spiess, Warthin, and others had given some figures. Morgagni was the first to point out that the kidney could be involved in a syphilitic process. Early writers of the eighteenth century did not recognize the condition. Rayer was the first to describe syphilis of the kidney clinically. Lancereaux, in 1861, wrote a fairly accurate account. After describing the pathology, the essayist stated that there were two types: (1) Early involvement, which might consist in a transient albuminuria, or acute or subacute nephritis. (2) Later involvement, which might be (*a*) chronic interstitial and parenchymatous nephritis; (*b*) amyloid kidney, or (*c*) gumma. In the transient albuminuria of early syphilis of the kidney there was little or no symptomatology. Acute syphilitic nephritis might occur even before the skin eruption of syphilis appeared, or it might occur three years after; the average time, however, was five months after the infection, and it rarely occurred after the first year. The first symptom was usually edema, which might go on to general anasarca, ascites, and hydrothorax. In some instances there was pain in the lumbar region, fever, and vomiting. The most striking feature, however, was the albuminuria, there being an enormous quantity of albumen in the urine. In the writer's case it was 3.2 per cent. Casts of all kinds were present but were not so striking as the albuminuria. If the urine was examined with the polaroscope double refractal lipoids would be found more abundantly in syphilis of the kidneys than in other kidney conditions. Renal function was less impaired than in other forms of nephritis. The writer gave a picture of the macroscopic and microscopic findings, and stated that they were not different from similar kidney conditions having a different etiology. It was important to differentiate syphilitic nephritis from that of other etiology. The prognosis of the early transient form was good. The prognosis was fairly favorable in the acute and chronic forms; unfavorable in amyloid kidney; favorably if recognized clinically in gumma. The treatment was both specific and general. Care should be taken in administering the specific because of its possible effect on the kidney. Frequent urinalysis and real function tests were imperative.

Dr. J. H. WITHERSPOON of Nashville, Tenn., cited the case of a man with kidney trouble and large amounts of albumin, who gave a history of having had syphilis twenty years before. There seemed to be a growth at the lower pole of the kidney. Catheterization of the kidneys separately showed that the largest amount of albumin was excreted by the right kidney but that the left was also involved. The question that came up was whether this was a late manifestation of syphilis whether a gumma was present and whether it was right to remove the right kidney when the left was also somewhat involved. The man gave a negative Wassermann and did not respond to specific treatment.

Dr. WILLIAM H. MERCUR of Pittsburgh confirmed what the reader of the paper had said with reference to the finding of very high degree of albuminuria in syphilitic nephritis without any other bad symptoms.

Dr. J. B. MCELROY of Memphis, Tenn., said he had seen several cases similar to the one described by Dr. Thompson. He thought there was nothing specific so far as the syphilis was concerned; that was, the cases when the condition was due to other causes. They were just like degeneration nephropathies in other conditions, as in tuberculosis and chronic suppurative proc- exhibited the same kind of nephropathies as were seen esses. He thought the entire group of nephropathies should be studied from a different standpoint and that it was time they dropped the classification of parenchymatous, interstitial and a great many other things in connection with nephritis.

The Effect of Tonsillectomy on the Recurrence of Acute Rheumatic Fever.—Dr. WILLIAM P. ST. LAWRENCE of New York presented this study which consisted in the analysis of scientific data concerning 75 children subject to recurring attacks of acute rheumatic fever and chorea, and others subject to attacks of tonsillitis, "growing pains," and myositis, making a total of 94 cases. The children comprised members of both sexes and ranged in age from four to fourteen years at the time of the operation. Tonsillectomy was performed from two to six years ago, at an average of three and one-quarter years ago. The tonsillectomies had been performed by the Sluder method and the adenoids removed by the adenotome. Since the operation these children had been seen at intervals of four or five weeks. They had been careful to see that there had been a complete removal of the tonsils. In one-fifth of the cases the tonsils had to be reoperated upon because a great deal of tonsillar tissue remained. Since the operation the condition in the throat had been studied particularly from the standpoint of infection, and observation had been made concerning the severity and recurrence of the so-called rheumatic manifestations. Many of the cases presented cardiac lesions, and observations had been made concerning the effect of the operation on the cardiac disease and on the occurrence of cardiac failure. In many cases in this series the tonsillar nodes were enlarged and following the operation the nodes had disappeared. In only one-third of the cases did palpable nodes remain and then they were greatly reduced in size. At times these nodes disappeared within three or four days of the operation. In 84 per cent. of the cases having rheumatic manifestations there had been no recurrence of the rheumatic attacks since the operation. Two-thirds of these cases had had the last attack of so called rheumatism within one month of the operation, and one-half of them had had recurring attacks for a period of two years previous to the operation. There was no better factor in the management of children with cardiac disease than the tonsillectomy. Whether this was the result of removing a toxemia he could not say, but the effect had been beneficial to these children. In cases of undernutrition the results of removal of the tonsils was equally striking. Pains in muscles, joints, and bones did not recur in 77 per cent. of the cases; in 50 per cent. of those having chorea there was no recurrence. In twelve children who had been in the ward with decompensation since the removal of their tonsils, at the end of three and one-half years only one had returned with decompensation, and these children had been watched every week. There were some few recurrences of rheumatism following tonsillectomy, so that while tonsillectomy had been the decisive factor in the improvement or cure of these children he would not say that it was the whole thing, but he felt convinced that it had an important bearing.

Dr. LEWIS A. CONNOR of New York said the tonsils were an important factor in the conditions mentioned and that their removal was an important weapon in the prevention of the recurrence of rheumatic manifestations. But this work of Dr. St. Lawrence's was valuable not because it concerned a great number of cases but because of the thoroughness with which the cases it did concern were studied. He had made close, careful, accurate observations. He had taken pains to see that the tonsillar tissue had been removed completely and he had waited patiently for sufficient time to elapse before drawing conclusions. He knew of no other statistical study that covered the ground in anything like the careful way in which he had covered it.

That was the reason why his figures were of such value. The work pointed a lesson of much wider significance than he had intended. It should serve as a model for statistical studies. Rheumatic fever we might take as the prototype of systematic infection and we seemed to be ready to accept the focus of infection as the origin of such general infections. It was therefore important that we should be able to give definite demonstrable proof of the relationship between the focus of infection and certain conditions; if we were ever to be rescued from the confusion and uncertainty that now surrounded the subject, it would be through just such examples of thorough discriminating statistical study.

Dr. Alexander Lambert of New York congratulated Dr. Lawrence heartily on his very excellent piece of work and referred to an investigation of the incidence of rheumatic fever at Bellevue Hospital published in the *Journal of the American Medical Association*, April 10, 1920, that investigation was undertaken to see whether there had been an actual diminution of the number of acute cases of rheumatism admitted to Bellevue Hospital and to see whether any deductions could be drawn from them as to the effect of dental hygiene and the spread among the profession of the realization of the relation of focal infection to general disease. A few of the statistics presented in that article were quoted which seemed to indicate that the striking diminution in the number of cases of rheumatic fever within the past two years was more than accidental for which dental hygiene more than any other one factor was responsible though it seemed that tonsillectomy had also made its impression. To settle the question as to the part played by the teeth and that played by the tonsils they would have to remove one thing only and note the result on the morbid process and in that way they would not get into a haze such as they were in at present. Dr. St. Lawrence had followed this plan and had done an excellent piece of work.

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

The Principles of Anatomy as Seen in the Hand. By Dr. Frederic Wood Jones. 325 pages. 123 text figures. Published by P. Blakiston's Son & Co., Philadelphia, Pa.

Regional Anesthesia. By B. Sherwood-Dunn, M.D. 294 pages, with 224 figures. Published by F. A. Davis Co., Philadelphia, Pa.

Manual of Surgery. By Dr. Albert Carless. 1558 pages. Published by William Wood & Co., New York.

Manual of Diseases of Children. By James Burnet, M.D. 416 pages. Published by William Wood & Co., New York.

Handbook of Skin Diseases. By Frederick Gardiner. 158 pages. Published by William Wood & Co., New York.

Handbook of Anesthetics. By J. Stuart Ross. 214 pages. Published by William Wood & Co., New York.

Cunningham's Manual of Practical Anatomy Revised and edited by Arthur Robinson. 451 pages. 203 illustrations. Published by William Wood & Co., New York.

Diseases of Women. By Dr. Charles M. Green. 466 pages, with illustrations. Published by W. M. Leonard, Boston.

Peking Union Medical College, Annual Announcement, 1920-1921, Peking, China. 64 pages. Peking, China.

Ninety-fifth Annual Report of the Managers of the Society for the Reformation of Juvenile Delinquents in the City of New York. 102 pages, with illustrations. Published by the New York House of Refuge Class in Printing, 1919.

Therapeutic Hints.

Acute Suffocative Catarrh.—Furlong cites a case of acute suffocative catarrh—a very rare condition, in his experience—in a man of 70. He injected at once 1/100 grain atrophine sulphate and 1/15 grain strychnine nitrate, and administered oxygen by inhalation. He also gave three separate dram doses of sal-volatile at intervals during the night. By the next morning the patient was practically as well as ever.—*British Medical Journal.*

Maternal Feeding of Infants.—J. D. Love of Jacksonville, Fla., in a discussion of some facts and fallacies relating to maternal feeding of infants, holds that the gross appearance of breast milk furnishes but an unreliable index as to its suitability for the baby. Before pronouncing milk as being too rich in quantity, the presence or absence of colostrum bodies should have been determined by microscopic examination. The mere fact that milk is scant in quantity furnishes no valid excuse for the withdrawal of the infant from the breast, but rather calls for supplemental feedings. Conclusions drawn from chemical examinations of breast milk, as usually practised, are apt to be misleading. Laboratory findings should confirm clinical observation. In influencing the quality of breast milk the maternal dietary, while of some importance, is a smaller factor than causes which operate through the medium of the mother's nervous system.—*Southern Medical Journal.*

Camphor.—Douglass W. Montgomery of San Francisco, discussing some of the medicaments used with success in the past, gives the following prescriptions containing camphor:

Rosacea.—In cyanotic cases of rosacea in which the skin is cool, often cooler than normal, hot soakings with borate of soda, or bicarbonate of soda solutions may be employed in the evening, followed by a salicylic acid lotion.

℞ Acid salicyl 0.5-1.00
Spts. camphoræ..... 25.00

An acetic acid lotion may be used instead:

℞ Spts. camphoræ
Aceti
Tr. benzoin āā10.00
Spts. vini dil.....150.00

The camphor modifies the acidity of the other two principal ingredients, salicylic and acetic acid.

Chilblains.—In this condition, which is an edematous fluctuation in the blood-vessels of the true skin, camphor is an old and much used remedy. It seems to act in causing resolution of the edema. and in relieving the irritability of the nerves. The following is Ewalt's formula:

℞ Camphor 5.00
Ol. terebinth 20.00
M. Sig.: Rub into the chilblains.

The camphor mitigates the irritation of the oil of turpentine.

Frostbite.—The following is recommended by Lederman:

℞ Camphor 5.00
Bal. Peru 2.50
Vaseline .....āā 50.00

ENCEPHALITIS LETHARGICA.*

BY EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL NEUROLOGY, COLUMBIA UNIVERSITY.

THE present epidemic of encephalitis lethargica has acquired prominence from its virulence, its widespread distribution, and the many forms in which it has appeared. The disease is not new. Conditions similar to it existed in Germany as far back as the seventeenth century, and in Italy and Hungary in 1890. The epidemics which were recognized and fully described occurred in Vienna in 1916-1917, in England in 1918, and in the United States in 1919. Outbreaks of the disease have at one time followed epidemics of influenza, at others epidemics of poliomyelitis. It is, therefore, not out of place to suggest that some connection may exist among the three diseases. There is a feeling held by many that influenza is a precursor of encephalitis, and by others that poliomyelitis and encephalitis are closely related, if not identical processes. It is not as yet possible to say just what connection, if any, exists between influenza and encephalitis nor whether poliomyelitis and encephalitis are one and the same.

The disease is an acute infection and like most acute infections is due to a specific virus. Strauss, a year ago, proved that an inoculation of emulsion of human brain produced lesions in the monkey characteristic of the lesions found in encephalitis and that washings from the nasopharynx in a case of encephalitis produced paralysis in the monkey. More recently he has obtained a filtrable virus from nasal washings which in 85 per cent. of the cases has given positive results in animals, and in the case of the spinal fluid 80 per cent. He feels justified in concluding from this that the virus enters the system through the nose, which fact he corroborates by calling attention to the frequency with which coryza ushers in encephalitis. The disease, is, therefore, infectious and probably mildly contagious. Two observers have reported more than one case occurring in a single family. Here in New York we have had two members of the house staff affected with it, one at Mt. Sinai, and one at Lincoln Hospital.

The pathological changes which encephalitis produce are inflammatory in character. Macroscopically the brain shows a considerable degree of edema and a marked venos congestion. Microscopically, there appears an infiltration of small round cells in the lymph spaces and especially around the smaller blood vessels and nerve cells. In addition to this, are numerous small hemorrhages, areas of necrosis, and a chromatolysis of the nerve cells. These changes are most evident in the basal ganglia and mid brain where the resultant congestion is greatest. However, from the reports of many observers, these changes are not limited to the basal ganglia but may occur anywhere in the nervous system.

The type of symptoms which occur in any particular case are dependent upon the particular part of the nervous system affected. Thus, if the disease attacks the globus pallida, tremor and rigidity will result; if it attacks the thalamus, choreiform movements will result, if the meninges rigidity occurs—if the spinal nerve roots, pain will result—if it attacks the cranial nerve nuclei, ophthalmoplegia, facial paralysis, and so on.

There are four cardinal symptoms. I do not mean that these four necessarily always occur but that they are usual, frequent, and typical. These are: (1) Ocular paralyses. (2) Hypersomnia. (3) Elevated temperature. (4) A change in the general state. Of these, ophthalmoplegia and hypersomnia usually attract attention first.

In addition to these there are several other important symptoms which I shall briefly discuss.

The Cranial Nerve Palsies.—The most frequent group of symptoms which occurs in encephalitis lethargica is an affection of one or more of the cranial nerves. Reports have been made of an involvement of all but the first. The third nerve is the one most commonly affected, giving rise to ptosis. This may be single or double, complete or incomplete, constant or transient. Next in frequency may occur paralyses of either the fourth, sixth, or seventh. These ocular paralyses often inaugurate the disease so that ptosis, double vision, or strabismus may present themselves even before fever or apathy. It is not at all unusual for paralyses of two or more cranial nerves to occur simultaneously, thus, I have seen patients with ptosis and a facial paralysis, with ptosis and an internal strabismus. Many patients complain of a slight dizziness, which may indicate an involvement of the eighth nerve. The ophthalmoscope does not reveal much; usually a congestion of the fundus and in two instances an optic neuritis. It has been suggested that the pain in the ear or on the side of the face, a symptom which some cases present, is indicative of an involvement of the fifth nerve. One can, of course, deduce a conclusion that the greater the number of cranial nerves involved, the more unfavorable the prognosis.

*Read at the annual meeting of the Medical Society of the State of New York, March 23, 1920.

Euphoria.—Euphoria is a very frequent symptom; in constancy it should rank next to the cranial nerve palsies. The large majority of these patients are without complaint; they say they feel well, and if not delirious, maintain that they are well. A few suffer from mental depression but a great many are neither unhappy nor in pain, except those afflicted with radiculitis. It is unusual to see a severe illness in which the patient is so little cognizant of his true condition; it is also unusual to find a disease in which the feeling of well being and the absence of any distress is so marked and so constant. For these reasons it is fair to place euphoria among the leading symptoms.

Rigidity.—There is often some rigidity. It is variable, inconstant, and irregular in distribution, and is of course dependent upon the meningitic involvement. The rigidity of the neck is rare and when present never as marked as that in tuberculous meningitis.

Slight or marked rigidity may affect the arms or legs. It often varies from day to day, and is a symptom of the second or third week of the disease.

Tremors, Spasms, and Choreiform Movements.—I have placed these physical signs under one heading as they are somewhat similar. The tremor which occurs in encephalitis is coarse and in many respects similar to that seen in paralysis agitans. In distribution, however, it differs from the Parkinson tremor. In the latter disease the onset is apt to be hemiplegic and the termination general, whereas in encephalitis the distribution is most frequently in the face and hands. In some cases the tremor appears at the very beginning, in some towards the end of the first week, while in others it is wholly absent.

The choreiform movements are irregular, jerky, and resemble those seen in Sydenham's chorea. They occur with great frequency and may be general or localized. Most commonly they are general. In those cases in which they are localized, the distribution is variable. I have seen cases in which the choreiform movements were entirely restricted to the abdominal muscles, and others in which they were restricted to the hands. In one instance I saw a patient with choreiform movements which involved only the muscles of the lips and the lower face so that the patient was constantly making grimaces very similar to the muscular movements made by a rabbit when eating. In another instance the movement was limited to one-half the body.

Temperature Changes.—Elevated temperature has been present in all of the cases which I have seen. Observers, however, have reported cases without temperature, so that fever should not be considered an essential of the disease. In those cases in which no temperature has been reported, it should always be borne in mind that the temperature may have existed before the patient came under observation, or at some hour between the readings. While temperature may not be considered as an essential, it probably does occur in more than five-sixths of the cases. The usual rise is to 101 or 102, but it may be less or more. It is a characteristic of the disease that the temperature may at any time suddenly rise to 103 or 104.

The facies of encephalitis lethargica is sufficiently characteristic to warrant a separate description. It varies with the different types. In the mild form or at the beginning of the disease, the skin may be natural in color or slightly flushed, and the ophthalmoplegia or facial paralysis alone stamp the disease. Gradually, as the condition advances, a lack of expression develops and finally the characteristic appearance. The classic facies of encephalitis is rigid, mask-like, and devoid of expression. The facial muscles are drawn downward, the skin is pasty and wax-like, and one or more cranial nerve paralyses distort the features. It closely resembles the facies of Parkinson's disease, with the addition of ptosis or facial palsy, and a skin gray and pasty. There is something very unmistakable about the immobility, the paralysis, and the grayness. As ptosis is the most common of the paralyses, it is usual to see these patients lying in bed with partly closed lids.

Apathy.—The apathy appears about the second week of the disease. It may be slight or intense, or it may be interrupted by an active and busy delirium. The most characteristic attributes of this lethargy are the lack of proportion between the real and apparent, and the ease with which the patient can shift from stupor to consciousness and vice versa. It is usual to see these patients roused and then relapse back into coma. They will wake, say that they are feeling quite well, take some nourishment, and immediately go back to sleep.

Eye Symptoms.—Among the eye symptoms are diplopia, nystagmus, fixed and unequal pupils. All of these have been observed. Diplopia is the most common; in fact, few cases occur without it, and it is frequent in about 60 per cent. of the cases. Nystagmus is most apt to be present in the Parkinson type.

Mental symptoms occur with great frequency. They may vary from a mild delirium to a condition of mania. The delirium is of the muttering, busy type; it is usually inconstant and may subside during the day. The patient chatters and mutters about his work and picks at the bed clothes. As the disease advances, the mental symptoms change. In the ordinary cases, apathy at first alternates and then wholly supervenes. I have noticed that a very active delirium, if prolonged, constitutes a prognostic sign of grave import. The mental disturbances most frequently appear in the first week of the disease.

Sphincter involvement occurs as a late, rather than an early symptom, and very rarely ushers in the disease. I did, however, see one case which entered the hospital for retention of urine.. I have seen three encephalitis patients in adjoining beds, each requiring catheterization. Involvement of the sphincters is serious from a prognostic point of view, and when accompanied by excessive temperature and increasing apathy, is apt to terminate fatally. Both sphincters become involved at about the same time.

Speech disturbances should be placed among the list of frequent symptoms. The type of disturbance is difficult to describe, as there is nothing quite like it. The speech is thick, difficult to understand, hesitating, and chopped off.

Laboratory Symptoms.—The laboratory does not help much in the diagnosis. The blood may show

a slight leuocytosis, but is otherwise negative, The spinal fluid shows a more or less marked pleocytosis, which is dependent upon the meningeal involvement. In the cases which I have seen, the cell numbers varied from fifteen to fifty and occasionally higher.

The pulse is rapid and hurries as the disease advances. It is usually considerably above 100 and may rise to 140 or 150.

There are *other less common* symptoms, among which I might mention as the most frequent pain, pupillary inequality, hiccoughing, exaggerated knee jerks, slight rashes, Kernig's sign.

The pain may be an initial symptom and may occur in the face, arms, or legs. It appears to be due to the radiculitis. It is sharp, very intense, and difficult to relieve. It is, fortunately, not of very long duration.

The occurrence of severe pains in the arms, legs, or about the face of the patient suffering from an acute infection, ought to suggest the condition of encephalitis lethargica. One might mistake neuralgia, sciatica, or even the pains of tabes for the radicular pain of encephalitis.

Inequality of the pupils, together with fixity of the pupils is not uncommon. The inequality is of longer duration than many other symptoms. I have known of one boy who, having been up and about for some weeks, still retain a marked degree of inequality of the pupils.

The knee jerks, in the majority of the cases, are apt to be unequal and vary during the course of the disease. This physical sign is not, however, of very long duration.

Kernig's sign and slight rashes appear but are infrequent. Herpes and a tache cerebrale have been reported.

There are *several types* of the disease. So far we have been able to recognize two which are very distinct, the slow and the rapid. The slow are gradual, and preceded by a period of malaise, coryza, and slight temperature. The slow type is difficult to recognize as it is insidious and at first suggests something akin to a mild influenza. It is as insidious and suggestive as is typhoid fever. The rapid cases are violent, fulminating, and self evident. They are frank and open declarations of a severe infection. It is in these that the mental symptoms are apt to be most pronounced, and most extreme.

I feel that in addition to these two types there should be recognized a third which one might denominate "the mild." I have seen cases in which there was a little temperature, a slight involvement of one cranial nerve, and a pleocytosis preceded by a mild and short-lived delirium and followed by slight apathy. The entire picture might be described as a miniature of the disease. These cases run a much shorter course and end in an uninterrupted recovery.

It is characteristic of both the slow and rapid types to have a prolonged convalescence accompanied by a recurrence or relapse of some of the physical signs. It is, I believe, a characteristic of the mild type to have a short and uninterrupted convalescence. In some of these mild cases, I have seen the patient improve decidedly in forty-eight hours.

The course of the disease in the pronounced cases is measured by weeks. So far as sex is concerned, in the cases which I have seen, the preponderance has been among males. Whether this is a coincidence or not, I cannot say. So far as age is concerned, my experience has been that the disease has been most apt to attack the young and the sturdy.

The prognosis is fair, sixty-five per cent. of the cases recover. There are one or two points which I might mention in this regard. The slow cases run a less severe course than the rapid, and in children the outlook is far better than in adults. A very low, as well as a very high, cell count is not favorable. Those cases in which the count is intermediate, that is ranging from 40 to 60, afford a much better prognosis.

41 East Sixty-third Street.

THE PREVENTION OF RESPIRATORY DISEASES IN INFANCY AND EARLY CHILDHOOD.*

By JACOB SOBEL, M.D.,

NEW YORK.

ASSISTANT DIRECTOR, BUREAU OF CHILD HYGIENE, DEPARTMENT OF HEALTH; PROFESSOR OF HYGIENE, FORDHAM UNIVERSITY, SCHOOL OF MEDICINE.

It is aimed in this contribution to discuss the prevention of respiratory diseases in infancy and early childhood, in other words, at that period of life under five years of age. By infancy is understood the period of life from birth to the completion of the first year, and by early childhood, that period of life from the second to the end of the fourth year. With the exception of this broad classification, of under one year, and from one to five years of age, no effort has been made to present the subject according to age groups.

The experience of most physicians who treat a large number of children coincides with that of Koplik, who states, "if we study the statistics of any large pediatric clinic, it will at once be apparent, that up to the tenth year of life, those diseases which affect the respiratory apparatus form nearly two-fifths of the cases." Rosenau says, "more people probably suffer from common colds than from any other single ailment. Could the sum total of suffering, inconveniences, sequelæ and economic loss, resulting from common colds, be obtained, it would at once promote these infections from the trivial into the rank of serious diseases. The common cold is not merely a congestion, it is an infection."

The fact that over 20 per cent. of all deaths under one year of age, in New York City, are chargeable to diseases of the respiratory system, and that 25 to 30 per cent. of all deaths in children under five years of age are due to these causes, to say nothing of the suffering, complications and sequelæ in the large number of cases in which recovery takes place, makes the question of the prevention of respiratory diseases in young children one of momentous importance, from the standpoint of the community or public health, as well as from that of the individual or family. The situation in New York City, to note it specifically, was as follows during the years 1917 and 1918:

*Read before the Harlem Medical Association, March 3, 1920.

Deaths in Children from Respiratory Diseases in New York City.

	Under 1 Year of Age.		Under 5 Years of Age.	
	1917.	1918.	1917.	1918.
Total number of deaths	12,563	12,657	18,265	21,019
Number of deaths from respiratory diseases	2,741	2,993	4,668	6,347
Percentage of deaths from respiratory diseases, based on total number of deaths, reported at that age	21.8	23.7	25.6	30.2

It is true that the percentage of deaths from respiratory diseases in children during 1918 was somewhat larger than during the recent previous years, owing to the inroads which the epidemic of influenza made upon the respiratory tract of infants and young children. Apart, however, from this unusual situation in 1918, the toll of deaths in young children from respiratory involvement is altogether too large, and admits of reduction through educational propaganda and other public health measures.

There was a time when the number of deaths from infantile diarrhea, commonly termed "summer complaint," was so great that it practically controlled the curve of infant mortality. Happily, as the result of a greater public knowledge of the importance and value of breast feeding, of a more rigid supervision, control and grading of the milk supply, of the recognition of the dangers of irregular and indiscriminate feeding, and of the education of the masses in the hygiene and the care of infants, the number of these cases, especially the severe and fulminating types of yester-years, is fast decreasing, so that in New York City, at any rate, and in many of the other more progressive cities, diarrheal diseases of infancy are third in the list of baby-killing diseases, with congenital diseases first and respiratory diseases second. In New York City, during the years 1917 and 1918, the infant mortality rate from diarrheal diseases was 19.1 and 14.7 respectively, per thousand children born, as against 19.4 and 21.7 respectively, for the respiratory diseases of infancy. Similarly, the death rate under five years of age, based on per thousand population at that age for diarrheal diseases during 1917 and 1918, was 5.5 and 4.1 respectively, as against 7.7 and 10.2, for diseases of the respiratory system. Those of us who are engaged in child welfare work in New York City, therefore, have come to look upon the respiratory conditions in infants and young children as the "winter complaint" and as calling for energetic efforts for its control, just as years ago our attention was directed to the "summer complaint."

It will be readily appreciated that the means for affecting a reduction in morbidity and mortality from diarrheal diseases in children are more direct, nearer at hand, and more easily controllable from a public health point of view than in the case of diseases of the respiratory tract. Many of the diarrheal diseases are directly traceable to impure milk, to improper or injudicious feeding, to carelessness or ignorance or neglect in the preparation of the milk or food, and in the sterilization of utensils necessary for said preparation, and to the indifference or disregard of the simple rules of child hygiene, all of which can be and are influenced more or less directly by sanitary regulation and popular education, either through personal contact of the population with the public health nurses, or through means of public lectures, distribution of literature, and newspaper publicity.

The means for the prevention or control of the respiratory diseases, on the other hand, are neither so immediate and direct, nor so easily approachable through the agencies of municipal authorities or private physicians. The control of diarrheal diseases, is, to a large extent, a question of cooperation of the mother, while the prevention of respiratory diseases is bound up with each and every member of the household and with the environmental conditions of the outside world; in other words, the opportunities for contact infection and for the dissemination of disease, are greater in the case of the respiratory tract than in diarrheal disease and in the large majority of other conditions. A child or an individual, ill with measles, diphtheria, smallpox, scarlet fever, infantile paralysis and kindred communicable diseases is usually acutely ill and is isolated from other members of the family and from the community at large. However, a person with an acute or sub-acute cold, or one who, in the ordinary course of events, coughs and sneezes or expectorates carelessly, is publicly at large, and each in his own way acts as a disseminator of infection. It must be remembered also that in the prevention of respiratory diseases the factors of immunity, susceptibility, predisposition, and even hypersusceptibility, play a far more important rôle than in diarrheal diseases. And yet, despite all this, there is a fertile field for successful accomplishment in the prevention of these respiratory diseases which every year cause the sacrifice of thousands of children's lives. I do not mean to imply that the methods of approach or the means at hand for affecting a reduction in child mortality, in the case of respiratory diseases, can be compared to those used in the case of diarrheal diseases, in the sense that we can expect as brilliant results in the former as have been achieved in the latter. That there is a possibility, however, of effecting a definite reduction in the mortality from respiratory diseases as well as from diarrheal diseases in the young, may be seen from the following:

City of New York.

	Mortality Rate Under 1 Year of Age, per 1,000 Births Reported.		Mortality Rate Under 5 Years of Age, per 1,000 Population.	
	Diarrheal.	Respiratory.	Diarrheal.	Respiratory.
1902	47.8	43.8	12.4	16.1
1917	19.1	19.4	5.5	7.7
1918	14.7	21.7	4.1	10.2
1919	15.9	15.5	3.9	6.0
Reduction since 1902, per cent.	66.0	64.0	68.0	62.0

In other words, there has been in seventeen years a reduction of 66 per cent. in the infant mortality rate from diarrheal diseases, and a reduction of 64 per cent. in the respiratory diseases, together with a reduction of 68 per cent. in the mortality from diarrheal diseases, under five years of age, and a reduction of 62 per cent. in the mortality from respiratory diseases, under five years of age. Certainly a reduction under one

year of 64 per cent., and under five years of 62 per cent. in respiratory diseases, warrants optimism for the future, rather than the pessimism which exists at the present time in so many quarters, as regards the control of respiratory diseases in the young.

The public, which has come to look with terror upon the dreaded "summer complaint," and which through bitter experience finally has learned the lessons of prevention of diarrheal diseases, has not as yet awakened sufficiently to the realization that respiratory diseases in childhood also can be prevented in a large measure, by carrying out simple lessons of child care. It is with the desire and with the hope of arousing interest in the necessity of making a definite impression upon the unnecessarily high morbidity and mortality from respiratory diseases in children that these lines are written.

Acute bronchitis and bronchopneumonia are the two diseases of the respiratory tract which most of all cause death in children under five years of age, according to official death certificates. Though given as a cause of death, bronchitis, in most cases, is probably a milder term for bronchopneumonia without definite physical signs—the capillary bronchitis of former days. These respiratory diseases in young children are either primary or secondary to the common forms of contagious diseases—measles, whooping cough, diphtheria, influenza.

When approaching the public in an educational way, the use of scientific terms or phrases seldom produces results; thus the use of simple or combined bacteriological terms, of toxines, antitoxines, immunization, phagocytosis, opsonic index, etc., are elevating terms, but the public wants something more tangible. The public should be told and will readily appreciate that whatever the specific cause of respiratory conditions, a favorable soil for the development of the causative germs must exist in order to produce disease; and just so far as this soil is made unfavorable for the many bacteria which are always present in greater or lesser numbers in and about all of us, waiting for a medium upon which to thrive, flourish and multiply, and just so far as the human organism is able, even in the presence of a favorable soil to ward off, withstand or modify this onslaught of bacteria and their by-products, in just so far will respiratory conditions be prevented or modified in severity. The essentials to drive home to the lay mind in any campaign for the reduction and control of respiratory diseases in infancy and childhood, are, to a large extent, those which the various departments of health throughout the country circularized during the last world-wide epidemic of influenza. In the case of children—and the younger the children the greater the need—these facts require special emphasis and application, since young children, because of their dependence upon parents, guardians, maids, or others, cannot protect themselves against the many sources of contact infection, either at home or in public.

It may not be amiss to state here that the term "contact infection" does not imply, as so many think, actual contact between sick and well, or between carriers and well, but rather close association between individuals. These essentials relate to general home and bodily cleanliness; thorough ventilation of the sleeping quarters; the admission of as much sunlight as possible into the sleeping and living rooms; the use of separate sleeping quarters, if possible; the avoidance of dry sweeping; protection from the dangers of coughing, sneezing, kissing and spitting; the use of individual handkerchiefs, or paper napkins or cloths, during the act of coughing, sneezing or expectoration; prompt disposal of nasal, oral and bronchial discharges; the use of separate eating utensils and the scalding or boiling of the same, after use; the avoidance of common drinking cups, towels, wash-cloths, and tooth-brushes; care of garbage and refuse; the prevention of fly-breeding, through cleanliness primarily, and of the entrance of flies through the use of screens or mosquito netting, secondarily; the avoidance of interchanging toys, pencils, edibles, etc.; isolation from the rest of the family of persons suffering from running noses, watery eyes, common coughs or colds; the avoidance of crowded places, especially the moving-picture houses of small capacity, and of children's parties; the importance of taking to bed immediately upon the onset of any acute condition of the respiratory tract and remaining there until well.

Coughs and colds are so frequently due to household infection that the home, especially in the case of children, should be regarded as the great source of spread. Most colds are domestic in origin, hence the term "household colds." Since, as aforementioned, the portals of entry for the more serious diseases of the respiratory tract are the nose and throat, and since sub-standard health invites infection, two main general considerations present themselves: (1) The need of placing the throat, nose, mouth and teeth in such condition, through nasal and oral hygiene, that the various bacteria which are ever present in large numbers in these localities, and many of which are capable of producing fatal diseases of the respiratory tract, will find the nose and throat less favorable for their development. (2) That by the avoidance of over-eating, over-exercise, fatigue, irritability and a lack of the necessary amount of sleep, the general body health may be kept at such a standard as to maintain sufficient resistance or reserve force to ward off diseases of the respiratory tract, or to minimize their effects if they attack an individual. In addition to the general preventive measures just outlined, there are special phases of prevention applicable to respiratory diseases in early childhood. The general preventive measures aforementioned apply, of course, to all periods of life, but in childhood certain extra precautions are indicated.

Infants and young children are far more sensitive to climatic disturbances than adults, and slight or moderate changes in temperature which would have practically no effect upon the adult, are often sufficient to give an infant or a young child a cold in the head. A cold in the nose in infancy and early childhood is dangerous because of the greater tendency of the process to extend downward to the lower respiratory passages. It

is for this reason that overheated rooms, overclothing, poorly ventilated sleeping quarters, inadequate covering or exposed feet, will often cause or rather pave the way for respiratory diseases in the young. Those who have had experience in the care of children have known the undue wetting of the head, as well as cold or wet feet and hands, to be followed by acute respiratory involvement. There are some who scoff at the idea that such trivial circumstances as cold feet or a wet head may lead to such involvement, and yet, no less an authority than Holt makes the statement that "cold feet are responsible for many attacks of colic and indigestion"; while Carr says, "cold feet are a common cause of catarrh of the mucous membrane." To cold feet may be added the chilling of the body surface, through damp clothing, wet shoes and stockings, wet diapers or bellybands, improper drying of the body after bathing, exposure during inclement weather, especially on raw and windy days, and the keeping of babies on windy street corners under the delusion that fresh air in itself, without regard to special climatic conditions, is free from danger. The foolish custom of exposing the lower limbs of children through the use of particularly abbreviated socks and sandals, is responsible for many of the inflammatory attacks of the mucous membrane of the respiratory tract. To be sure, "cold feet" have been responsible for a great many more and worse things in the general walks of life than colic, indigestion and colds; but that such a condition may prove a forerunner of serious respiratory diseases in infants and young children, of this I am firmly convinced from practical experience. It is reasonable to assume that in the case of an infant or young child, with cold or wet feet, head, or other part of the body, there is a disturbance of equilibrium of the circulatory mechanism, and that as a result of contraction of the blood vessels in a particular part of the body, there ensues a corresponding congestion of some other part of the body, be it nose, throat, stomach, bowels, or lungs. This explanation may appear somewhat crude, and for this reason the viewpoint, which has a more scientific tone, is presented as quoted by Rosenau: *"Exposure to wet and cold,* especially in combination, is a frequent source of lowered resistance. The exact way in which such exposure acts is not definitely known, but laboratory researches offer material for a number of suggestions. Emery sums up our knowledge upon this subject as follows: 'Immunity is to a very large extent a function of the leucocytes which are specialized cells to which the defense of the body is entrusted. Now, the functions (movement and phagocytosis) which can be easily investigated, are found to be dependent in a very high degree to temperature, acting best at the temperature of the body, or slightly above; and it is highly probable that the more subtle functions of the leucocytes may be similarly depressed by a low temperature. The exposure of the skin to cold, especially if the animal heat be abstracted more quickly by evaporation of moisture on the surface, will lead to a cooling of the blood which cirulates through it, and hence to a slight, though appreciable, cooling of the whole blood. This, it is true, is soon compensated for, and no great amount of cooling of the whole body occurs; but, even so, it is quite possible that periodic chilling of the leucocytes during their repeated passages through the cold skin may be sufficient to diminish greatly their functional activity, and to lower the resistance to a point at which infection may occur, and when once pathogenic bacteria have gained a foothold the resistance will for a time tend to decrease. There is also some evidence going to show that exposure to cold may lessen the production of the defensive substances which occur in the blood (alexin, antibodies, etc.), though this is not fully proved. It is worthy of note that the loss of immunity due to the action of cold and wet on one part of the body (such as the feet) is a *general* one, and may result in a nasal catarrh, an attack of pneumonia, acute rheumatism, etc., according to the nature of the infection at hand.' "

Another ingenious explanation and one quite the opposite of this, is presented by Mudd and Grant (*Journal of Medical Research*, 40: 53, May, 1919). These investigators proceeded to show that chilling of the body surface causes a reflex vasoconstriction or ischemia in the mucous membrane of distant parts of the body, such as the naso- and oropharynx, tonsils, etc. They contend that the ischemia incident to the cutaneous chilling, "by decreasing cell respiration or by retarding removal of the products of cell metabolism, or by increasing the permeability of the epithelial cell surfaces to bacterial products, or by decreasing the local supply of antibodies, or by altering the media of the tonsillar crypts and folds of pharyngeal mucosa in which bacteria are living, or by a combination of such factors, so disturbs the equilibrium between the host and the microorganisms as to excite infection." It therefore appears from a scientific as well as from a practical standpoint, that chilling of the body surfaces, whether because of increased local congestion or of ischemia, is a predisposing factor to the development of respiratory involvement, in that it produces conditions favorable for bacterial attack.

Pneumonia is by no means an uncommon condition in the new-born or during the first few months of life; much of a preventive nature can be done at this time. The practice of having the delivery room too cool is far more common than it should be, and in many instances this is responsible for pneumonia in the new-born, especially in premature or weakly infants. The delivery room should be well aired but warm; mothers can stand the warmth; babies must have it. A temporary chilling of the infant's body is sufficient in many cases to cause pulmonary congestion and subsequently pneumonia. New-born infants should be carefully covered with blankets immediately after birth, and a warm water-bag, *carefully protected*, should be *cautiously* applied to the extremities. I have seen several cases of pneumonia in the new-born where failure to carry out these simple precautions was responsible for respiratory disease. Atelectasis of the new-born and aspiration-pneumonia—intake of blood, mucus or liquor amnii—are conditions which are preventable in many instances if the labor is con-

ducted with scientific precision, or if in prolonged labor with delayed respiration or asphyxia, energetic post-partum attempts at artificial respiration with a catheter or the use of a pulmotor, are promptly or persistently applied. I have great confidence in the use of a soft rubber catheter, 14-French, directed along the course of the finger to the epiglottis and aspiration at the distal end, for removing inspired material. I feel convinced that its more general use in cases such as aforenoted, will prevent many cases of telectasis and aspiration-pneumonia in the new-born.

Commendable as may be the custom in maternity institutions of placing the infants shortly after birth in the nursery, away from the mother, to be brought to and fro through the hallways, sometimes from another floor, at nursing time, I cannot help but feel from my own experience that this is responsible for much of the snuffles, nose colds, bronchitis, if not for some cases of pneumonia, seen in this class of infants. In general, infants do not stand chilling well, whether it be chilling of the entire body or certain parts of it, and for that reason uniform body warmth is so essential. I have known infants and young children in whom the use of an excessive amount of cold water to the head or even lukewarm water for that matter, or an undue amount of perspiration, yes, even cutting the hair short, has been followed by acute rhinitis, angina or bronchitis. So, too, many overclothed infants and young children suffer from undue perspiration with subsequent chilling of the body, which is followed by colds. The occurrence of rhinopharyngobronchial conditions, following wet or cold feet, is so common as to call only for mention without comment. The lessons to be learned from these cases are self-evident.

At this point I should like to mention a condition which, in my experience, is not uncommon and which is frequently overlooked or diagnosed improperly. I refer to acute adenoiditis. Because of circumstances aforenoted—chilling of the body, excessive perspiration, undue exposure, wet or cold head, hands or feet—there occurs a congestion and catarrhal inflammation of the lymphatic nodules in the postnasal space. This condition may occur either with the normal lymphatic tissue or with nodules that are pathological in size or number. This adenoiditis or retronasal angina, as it has been called, is nothing more than an acute cold in the nose, with special involvement of the postnasal space, giving rise in nurslings, or in those bottle-fed, to difficulty in breathing, to fever of an intermittent or remittent character, gastric symptoms, nasal discharge, enlarged glands, and not infrequently earache, with redness of the tympanic membrane. These youngsters do not look particularly sick in the majority of cases, but they seem very much distressed; they are restless, irritable, toss about a great deal, and seem drowsy. Teething, bronchitis, autointoxication, febricula (whatever that may mean) are the diagnoses which are given in many of these cases. A careful regard for the warmth of the hands and feet and the body surface, will prevent this annoying and distressing condition in childhood.

Bronchitis, as such, is not a fatal disease in infancy and childhood; it may however, because of lack of care, be the forerunner of pulmonary disease. Given a case of bronchitis, certain simple precautionary measures have been found advisable in my experience; first, the administration of a liberal dose of castor-oil; second, the placing of the patient in bed under cover and under uniform warmth in a properly ventilated room. These two measures will often be all that is necessary, in addition, of course, to carefully regulated diet. The use of castor-oil has several advantages (a) in that it clears the intestinal tract of mucus which is swallowed by those of tender age, thus preventing intestinal fermentation with its attendant flatus and secondary embarrassed respiration, and (b) in that it has an expectorant action upon the bronchial secretion which is not generally appreciated. Those of us who served our apprenticeship in the children's dispensaries of long ago will remember the well-known and widely used cough mixture of that pioneer pediatrician, J. Lewis Smith, composed of syrup of ipecac, sweet spirit of nitre, castor-oil, and syrup of tolu. Dr. Smith knew the value of castor-oil as an expectorant, and many children were benefited because of his keen therapeutic insight.

It may seem farfetched to place children in bed for a mild attack of bronchitis, but I am firmly convinced that this measure alone is all-important, far more so even than medication. In the spring, fall and winter months, the rooms in the modern apartments, or in private houses for that matter, show varying degrees of temperature—some are warm, others are cool, and others are cold. To carry an infant in arms from room to room, through unevenly warmed hallways and rooms, or to have the runabout go from room to room, produces a chilling of the body in these youngsters and a disturbance of the circulatory balance which increases the pulmonary congestion and aggravates the existing bronchitis, if it does not eventually produce pneumonia.

My plea is, therefore, for placing young children in bed at the first signs of a cold, whether it be nasal, pharyngeal, bronchial or any combinations thereof. I recognize the difficulty of keeping runabouts in bed unless they are very ill. For that reason I have attempted to train the children under my care to "like the bed" as it were, by having the parents keep them in bed, part or the whole of one day every month, or more frequently, when they are well, furnishing them at the time with necessary toys to keep them occupied. By this means they are given a rest which certainly conserves their energy, and the taking to bed a the time of bronchitis or any other simple ailment does not appear as a hardship, but rather as part of their mode of life.

What is commonly called a "cold" is infectious and contagious, or better, let us say, communicable, and the same precautionary measures should be exercised for all members of the family, and particularly for the younger members, as in the case of contagious diseases. Children should be kept away from all adult members of the family or older children who present any suspicious signs or symptoms of nasal or bronchial catarrh. The affected individual should have his own bed, a

separate room, if possible, separate handkerchiefs, cloths or paper napkins, towels and eating utensils. All discharges should be collected on paper napkins or small pieces of gauze, and subsequently destroyed by burning. Handkerchiefs, if used, should be boiled. Kissing should be avoided during health as during illness. Promiscuous handshaking should be discountenanced and discontinued as a custom, for, after all, it is only a custom. Breiter, as far back as 1897, in an article entitled, "The Hand as a Propagator of Microbic Disease—A Medico-Social Question" (MEDICAL RECORD, December, 1897) called attention to this phase of the subject. Hand-to-mouth infection is a most prolific source of diseases of all kinds, and particularly of respiratory disease, and it would be better for us as a nation, if we were to adopt the Chinese method of greeting, which consists of placing the fingers and thumbs of the hands together in front of the body and bowing before the one greeted.

Babies and young children seem to feel instinctively that the mouth is meant as a receptacle for all manner of things besides food, and care must be exercised in preventing them from placing therein fingers, pencils, toys, clothing, and what not, particularly "what not." The runabout age of children is notable for what has been termed by Feer, the "Filth Infections." It is at this period of life that children infect themselves with dust and dirt, either at meals, at play or in their association with others. Swapping partly eaten articles of food, toys, etc., at this time and during school age, should be interdicted.

Few realize, perhaps, how much saliva there is extant. Therefore, I cannot refrain at this point from quoting part of Chapin's description of how diphtheria and other infections contained in the secretions of the nose and throat may be disseminated:

> Not only is the saliva made use of for a great variety of purposes ,and numberless articles are for one reason or another placed in the mouth, but for no reason whatever, and all unconsciously, the fingers are with great frequency raised to the lips or nose. Who can doubt that if the salivary glands secreted indigo the fingers would not continually be stained a deep blue, and who can doubt that if the nasal and oral secretions contained the germs of disease, these germs will not be almost as constantly found upon the fingers? All successful commerce is reciprocal, and in this universal trade in saliva the fingers not only bring the foreign secretions to the mouth of their owner, but there, exchanging it for his own, distribute the latter to everything that the hand touches. This happens not once but scores and hundreds of times during the day's round of the individual. The cook spreads his saliva on the muffins and rolls, the waitress infects the glasses and spoons, the moistened fingers of the peddler arrange his fruit, the thumb of the milkman is in his measure, the reader moistens the pages of his book, the conductor his transfer tickets, the "lady" the fingers of her glove. Everyone is busily engaged in this distribution of saliva, so that the end of each day finds this secretion freely distributed on the doors, windowsills, furniture and playthings, in the shops and public buildings, and indeed, upon everything that the hands of man touch. What avails it if the pathogens do die quickly? A fresh supply is furnished each day. Besides the moistening of the fingers with saliva and the use of the common drinking cup, the mouth is put to numberless improper uses which may result in the spread of infection. It is used to hold pins, strings, pencils, paper and money. The lips are used to moisten the pencil, to point the thread for the needle, to wet postage stamps and envelopes. Children "swap" apples, cake and lollypops, while men exchange their pipes and women their hatpins. Sometimes the mother is seen "cleansing" the face of her child with the saliva-moistened handkerchief, and perhaps the visitor is shortly after invited to kiss the little one.
>
> Children have no instinct of cleanliness, and their faces, hands, toys, clothing, and everything that they touch must of necessity be continually daubed with the secretions of the nose and mouth. It is well known that children between the ages of two and eight years are more susceptible to scarlet fever, diphtheria, measles, than at other ages, and it may be that one reason for this is the transfer of the secretions. Infants do not, of course, mingle freely with one another, and older children do not come in close contact in their play, and they also begin to have a little idea of cleanliness.

The use of the pacifier or artificial teat or dummy is a common cause of spreading disease and is mentioned only to condemn it. It is a source not only of infection of the mouth, throat and bronchial tract, but its continued use predisposes to congestion of the postnasal space and the development of adenoids, at least an hypertrophy of the normal adenoid tissue in the pharyngeal vault.

Domestic pets are a more frequent cause of acute coryza than is generally supposed or admitted. It is well known that dogs and cats contract whooping-cough and diphtheria, and still better known that they disseminate skin diseases, such as ringworms, favus, etc. Sneezing and coughing in dogs are not uncommon. Attention has recently been called by Roberts (*New York Medical Journal*, July, 1919) to the fact that 90 per cent. of cats and dogs are infected with a specific bacillus producing a contagious form of nasal catarrh and with mixed types of streptococci. The close association of children and adults with these animals is undoubtedly responsible for the production of a large number of nose colds. The undue fondling, kissing and sleeping with dogs should be prohibited by physicians wherever and whenever possible.

In all centers, such as dispensaries, baby health stations, schools, day nurseries, etc., where large numbers of children and adults congregate for treatment or supervision, it is incumbent upon those in charge to dispose of individuals having coughs or colds as soon as possible. The clientèle should be inspected as a group, by a physician, nurse or matron, and those affected with coughing, sneezing or watery eyes should be examined or treated at once or otherwise disposed of. Similarly, wherever possible, overcrowding of these centers should be avoided, particularly when respiratory diseases are prevalent, by so arranging the clientèle that their visits are spread over the morning and afternoon, instead of having them all gather together at one time. Mothers should be instructed to send or bring to these centers only the children registered. These centers should be frequently and thoroughly aired and carefully cleaned with washing soda water or moist moppings, and as much sunlight should be admitted as possible. Sunlight as a destroyer of germs, a purifier of atmosphere, an enemy of humidity, is not sufficiently appreciated. Remember the Italian proverb, "Where the sun does not go the doctor does."

Most of the foregoing statements relate to the predisposing factors of respiratory diseases. There are certain types of children who are particularly susceptible to pulmonary involvement and in whom special care must be exercised. These types as a class present conditions in which there is a weakness of the general muscular apparatus and particularly that of the chest wall, combined with an abnormal flexibility of the ribs, all of which induces to a respiratory insufficiency. It is for this reason that infants and young children with rickets, myxedema, mongolism, infantilism, prematurity and syphilis often succumb to diseases of the respiratory tract. Any condition which lowers the muscular tone of the chest wall and prevents the proper and necessary intake of air and the expiration of organic and other matters renders the child liable to pulmonary disease. These children must be carefully guarded against outside influences which predispose to coughs and colds. In fact, one of the most frequent causes of death in premature infants is infectious bronchopneumonia, and this, because the lungs are not fully formed, because the muscular apparatus suffers from inertia and because the respiratory movements are superficial and shallow. As a result of the predominance of rickets among the Italians and negroes, we find that this class of children contributes a large percentage of deaths from respiratory diseases under ten years of age. The mortality from acute respiratory diseases in children, from the standpoint of parental nativity, is thus noted by Guilfoy: "The spectacular mortality from acute respiratory diseases among children of Italian mothers stands out boldly in the tabulation of rates from the diseases acute bronchitis and pneumonia. It is more than three and one-half times that of children of Russian, Austro-Hungarian and Irish mothers and a little more than double that of American mothers.

"In discussing the mortality from the infectious diseases, it was shown that children of Italian mothers head the list, and this partly explains the high mortality from bronchitis and pneumonia among these children, as these latter diseases are sequelæ to that most contagious disease of childhood—measles. In addition, the Italian mothers take steps to prevent the entrance of cold or fresh air into their apartments, during the spring and winter seasons, and, in consequence, their children are rendered susceptible to infection by the pneumococcus."

All diseases which are nutritional or metabolic in their origin carry with them a reduced vitality or resistance and thereby an increased susceptibility to respiratory infection. Children who suffer from the exudative diathesis also appear susceptible to coughs and colds, particularly if this predisposition is directed toward the respiratory tract instead of toward the stomach, intestines, skin, etc. This diathesis is frequently familial; the attack of cold or bronchitis in these cases often comes on without apparent cause and the knowledge of the existence of such diathesis in other members of the family is important in taking active measures of precaution in the infants and young children. Indeed, there are families in which all or many children are predisposed to frequent involvement of one part of the body or the other. Herrman has reported a family in which the children of four successive births died of pneumonia within two weeks after their birth, and in addition one died at three weeks of age, one at ten weeks of age, and one at eleven months of age, and in which neither the labor, the hygenic conditions, character of feeding, nor mother's milk seemed to be at fault. He attributes these multiple deaths to "an unusual susceptibility of the respiratory tract."

Gastroenteritis in early childhood is also a predisposing factor of pulmonary diseases. Some of these cases develop a severe and fatal pneumonia. Unnecessary and too frequent rectal irrigations with undue exposure and chilling of the body should be avoided. The tendency to subnormal temperature, because of extra loss of fluids and the inanition following the difficulty in feeding should be guarded against by the use of proper protective covering, warm drinks, hot-water bags, enteroclysis or hypodermoclysis, careful feeding, etc.

Bronchopneumonia is frequently secondary to measles, whooping-cough, influenza and diphtheria. Its prevention is largely, of course, a matter of the proper treatment of the original condition. There is a tendency these days with many physicians and many of the laity to allow these children out of bed or the house too soon. The rash of measles is not limited to the cutaneous surface and its disappearance from the skin does not necessarily mean its entire disappearance from the delicate and sensitive bronchial mucous membrane; besides the mucous membranes do not recover from the effects of the rash as quickly as the skin surface. It may appear an exaggeration to say that the child with measles should be kept in bed or indoors for at least ten days after the temperature has become normal, but our experience in the 1918-1919 influenza epidemic taught us that countless lives were sacrificed at the beginning of the epidemic because of the failure of the profession and the laity to recognize the importance of this fact.

The pneumonias which follow measles, whooping-cough, influenza and diphtheria, are frequently so desperate and so often fatal, that it is better to err on the side of caution and to keep the children under close surveillance, rather too much than too little.

The prevention of respiratory diseases in infancy and early childhood is correlated in a way with tuberculosis, at this time of life, and for that matter at later periods, in that repeated attacks of bronchial or pulmonary disease, especially those following measles and whooping-cough, predispose to tuberculosis. It may perhaps be more correct to say that repeated colds bring out a latent infection of early infancy, for it is now recognized that "human infection by tubercle bacilli takes place usually during infancy or early childhood" (Hess). Apart from the dangers to infants and children attendant upon close association with adult members of the family suffering from common colds, cough and expectoration, it is important to remember that many sources of tu-

berculous infection in children are traceable, as Hess has shown, to contact with "communicable but undiagnosed tuberculosis."

As Hess states, "there is a clinical basis for this point of view. It is within the experience of most physicians that persons in apparently normal health may show tubercle bacilli in the sputum. . . . It seems probable that there are many individuals who from time to time excrete tubercle bacilli, who are occasional shedders, if we may use that term, of tubercle bacilli, and who are responsible for the large numbers of reactions encountered among children tested with tuberculin. . . . It does, however, emphasize the fact that where there are young children we should watch more carefully for a communicable tuberculosis among the adults of the household who suffer from apparently harmless catarrhal respiratory infections."

No attempt has been made in this contribution to cover the subject in its entirety. It is hoped, however, that these remarks will lead others to give added impetus and attention to the subject of respiratory diseases in infancy and childhood, with the ultimate reduction in both their morbidity and mortality. Prevention here is more a matter of education than of compulsion and legislation, for it is hard to legislate righteousness, common sense or the golden rule into most people.

140 West One Hundred and Twenty-second Street.

THE SKIN AS AN INDEX TO HEALTH.*

By MOSES SCHOLTZ, M.D.,

LOS ANGELES, CAL.

INSTRUCTOR OF DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, UNIVERSITY OF SOUTHERN CALIFORNIA; DERMATOLOGIST TO GRAVES DISPENSARY, MEDICAL DEPARTMENT OF UNIVERSITY OF CALIFORNIA AND TO THE KASPARE COHN HOSPITAL.

The problem of valuation of the skin, as an index of health, is a subject of great practical interest to a clinician. The consideration of this problem in its clinical aspects can be properly prefaced by a few general remarks.

Physiology of the Skin.—It is important to keep in mind the peculiarities and unique characteristics of the skin, as an organ of the body. Skin is the only organ diffusely distributed over the whole surface of the body. It is also the only organ that has so many physiological functions to perform. Serving as the protecting encasing of the body, as the seat of tactile, sensory, and sexual nerve endings, as the respiratory, thermoregulating, and eliminative organ, the skin, obviously, must be of a paramount importance in the general human economy. The enormous surface of its vascularization and innervation renders easily understandable the intimate physiological interrelationship between the skin and the rest of the body.

Pathology of the Skin.—This anatomic fact renders plausible the expectation that the skin can serve as a surface indicator of visceral disorders and that a skin disease can be interpreted as a danger signal from within. In fact, this idea has taken such a hold on the layman's mind that nine out of ten patients seeking advice for a skin disease begin their recital of woe with a question: "Doctor, don't you think I need a blood medicine?" This conception of skin disease, as the projection on the surface of internal disorders, has led to the theory of elimination of the body impurities through the diseased areas of the skin. It largely accounts for the reluctance on the part of many laymen to have their skin diseases treated from fear to aggravate the internal condition by the stoppage of elimination and by the closing in of these impurities. This medical superstition, harking back to the medieval humoral pathology, needs hardly any refutation before an intelligent medical audience. However, the survival of this idea still can be seen in the practice of many practitioners in their overemphasis of the systemic treatment over the local in skin diseases.

A factor of tremendous importance for a clear understanding of the skin pathology is the peculiar topographic location of the skin in the human economy, which renders it subject to all kinds of mechanical insults, of chemical and physical irritants. Atmospheric influences, cold and heat, wind and sun rays, normal and abnormal secretions of the human body, a great variety of animal and vegetable parasites, and last but not least, that specific dermatological insult—scratching, due to an intolerable itching, all these influences tend to keep up and to intensify the primary morbific impulse set in motion by a systemic or local factor. Thus a vicious circle is created which tends to perpetuate itself and which can be broken most effectively only by being attacked from both ends, *i.e.*, by applying simultaneously, both the systemic and the local treatment.

Local vs. Systemic Dermatoses.—The first step in valuation of the skin as the index of health should be to determine how many of skin diseases are of local origin and distribution and how many are of systemic. It may be of interest to note that of some 200 nosological forms accepted by the American Dermatological Association more than two-thirds are purely local in origin or distribution, and that less than one-third are of systemic origin. Yet it would be a grievous fallacy to take these statistical inferences at their face value. First, it should be remembered that dermatological classification is based essentially on morphological and histopathological differences and not on etiology and pathogenesis. It stands to reason that local dermatoses, being of a more constant morphological design and of slower histopathological changes, lend themselves more readily to a morphological and pathological differentiation. So it came that local dermatoses were accorded more morphological study and that their classification was much quicker and easier attained than that of more elusive and morphologically inconstant systemic forms.

To local dermatoses belong mainly parasitic skin diseases, affections of skin appendages (hair and glands), tumors, local atrophies, and degenerations. Among systemic or symptomatic dermatoses most important and common are: syphilis, tuberculosis, scarlatinoid erythemata, urticarias, eczemas, psoriasis, dermatitis, herpetiformis, pemphigus, erythema multiforme, Raynaud's diseases, drug eruptions, pigmentations, and generalized atrophies.

The number of systemic dermatoses is small in-

*This paper was read before the winter session of the Southern California Medical Society, December 3, 1919, in Los Angeles, Cal.

deed, but so common they are, so difficult of detection are their underlying constitutional factors, and of such vast importance are they to the general economy that their clinical importance easily tops over that of the numerous but easily identified and easily controlled local dermatoses. It is true, the dividing line between systemic and local dermatoses can not be sharply drawn. The most common example would be when persistent and distressing itching robs the patient of sleep and affects his general condition. The absorption of pus from staphylococcic or streptococcic skin infection may bring fever with a subsequent train of constitutional symptoms. A parasitic skin affection, such as blastomycosis or sporotrichosis, from a superficial and purely local condition may metastasize and become systemic with a fatal issue. A harmless looking seborrheic wart may turn into a keratosis, then into an epithelioma which, if unrecognized or mistreated, invades the lymphatics and is transformed into an inoperable visceral carcinoma.

On the other hand systemic dermatoses often present local factors in a striking and heretofore unexplained manner. For instance, it is easy and natural to conceive the infectious exanthemata to be manifested by an universal diffusely distributed eruption; it is equally plausible that toxic rashes and eczemas should be of generalised diffuse character. But how can we explain that the unquestionably systemic dermatosis, psoriasis, has such a marked preference for the knees, elbows, and other extensor surfaces? Why the equally unquestionably systemic dermatosis, erythema multiforme, has a selective distribution on the back of the hands, tibial surfaces, and neck? Why again lichen planus, also due to toxic influences, preferentially starts on flexor surfaces of the forearms and legs? Why so many dietetic and toxic eczemas recur on the same limited areas of the skin? Whether we shall explain this selective localisation by a mechanical irritation or by a trauma, by local vasomotor, neuratrophic reflex influences, or by any other hypothesis, the unavoidable inference is that the systemic factor alone is not sufficient to precipitate the breaking out of skin lesions unless certain local factors determine its localisation.

Local vs. Constitutional Treatment.—In application to therapeutics this means that the detection and elimination of a systemic underlying etiological factor is more of a preventive than of a curative value: It will prevent a recurrence but it may not and in many cases does not clear up the present local lesions because the local resistance and vitality are not altered by the constitutional treatment.

Another potent and specific reason why constitutional treatment alone can not clear up local lesions has been mentioned before. This is the peculiar exposed location of the skin in the human economy which renders it subject to a constant exposure to all kinds of external irritants. Even should a local lesion be caused entirely by a systemic factor, once started it evolves a secondary chain of pathological changes of its own, independently of the systemic factor that had originally started it. These secondary pathological changes may consist of chronic cellular infiltration, lichenification, infection with streptococci, seborrheic contagion, etc. To combat this local factor one must not only break up the vicious circle of local irritation produced by the interplay of itching and scratching, not only meet all secondary local developments and the individual indication of the case, but above everything else one must strive for a local stimulating and alterative effect to raise the local resistance and the recuperative power of the affected area. This alterative effect of cellular stimulation is obtained best by the exposure of the affected area to the actinic rays of the *x*-ray or ultraviolet light. Both of these agencies are the best weapons in the dermatological armamentorium, and they can be truly called the specific biological cellular stimulant of chronically inflamed tissues. Thus the best and the quickest results in systemic dermatoses can be obtained by the simultaneous application of both constitutional and local treatment.

The Semeiological Service of Dermatology to General Medicine.—The preceding remarks give a sufficient insight into the correlation between the pathology of the skin and that of the general economy to warrant the attempt at a valuation of the skin as the index of health. That the skin reflects in a general way the state of general health has been accepted by the laity and the profession alike as a hygienic axiom. This is what the layman calls a pure complexion in healthy, and sallow dirty in chronic invalids.

The professional mind naturally looks to dermatology for more definite and specific indications of systemic disorders. The ideal of skin semeiology from the point of view of an internist would be to have a well defined dermatological design corresponding to every type of visceral disorder.

Unfortunately this ideal can never be attained, because there is no specificity between the morphological type of dermatological lesions and the pathogenetic factors responsible for them. Not only the same etiological factor can produce different types of skin lesions, but *vice versa* the same type of skin lesion may be produced by different etiological factors.

The old time conception of skin disease, as a rigid and fixed pattern, remaining stationary throughout its course, has been abandoned for good. The modern dynamic viewpoint in general pathology has modified this conception to the extent that skin disease, as a clinical entity, retains its essential morphological characteristics and traits, but its clinical picture may present infinite variety and modifications depending on secondary changes, location, and peculiarities of the individual case.

Therefore, while dermatology at the present time is not able to furnish the internist with a clear-cut and numbered specimen of a skin picture for each systemic disorder, it does offer to him several groups of clinical skin characteristics and morphological traits for various systemic pathological conditions. These dermatological symptom-complexes or syndromes possess, some of them pathognomonic, and others merely suggestive diagnostic value. If persistently looked for and carefully analyzed, they can be of enormous clinical assistance in detecting various visceral disorders.

Dermatological Syndromes of Systemic Significance.—Up to the present the number of these syn-

dromes is small, but the systemic pathogenetic factors revealed by them are so destructive and universal, and the number of the cases falling into these groups is so enormous, that the practical value of these syndromes is great indeed.

Syndrome of Syphilis.—Possibly the oldest and the best established of all is the syndrome of syphilis. It is surprising to what little extent it is utilized by the general profession. Only the frankest and the most exquisite in type lesions are used for the clinical diagnosis of syphilis. Yet the specific traits of cutaneous syphilis can be expressed in very few words. They are: dusky red, raw ham, or copper color, sharply defined borders, deep cutaneous and subcutaneous infiltration, tendency to form flat lesions, serpiginous, kidney-shaped, or circinate in shape; in the later stage tendency to ulcerate and to form soft, gradually depigmented, wrinkled scars of a cigarette-paper variety.

These specific stigmata in various combinations and grouping are found in practically every case of skin syphilis, and are pathognomonic. In view of this it is a matter of wonder and regret to see how much stress is laid my many practitioners on the specific history and how faithfully they cling to the habit of questioning into the venereal past of the patient. What a futile and perfectly useless expenditure of time and energy on the part of a physician to play detective and to pry into the venereal past of the patient when he has at his command means of objective diagnosis, infinitely more reliable and promising of results! It is neither scientific nor practical to predicate a diagnosis on the veracity, memory, and power of observation of the patient. It is a common experience that the primary syphilitic lesion is more often overlooked and ignored than any other. Even secondary generalized rashes and mucous patches are not uncommonly overlooked or misinterpreted and forgotten by the patient. Instead of questioning and cross-examination a physician should strip and carefully examine the whole surface of the body, searching for any evidence of cutaneous syphilis. One is rewarded for his efforts more often than it would be expected, by finding either an active lesion or valuable retrospective evidence in the form of leucodermatous spots or kidney-shaped, soft, flexible, atrophic, pigmented, or depigmented scars.

Another factor commonly abused in the clinical diagnosis of cutaneous syphilis is the Wassermann test. There is a tendency on the part of many practitioners to shirk the burdens of clinical diagnosis by accepting unreservedly the dictum of the laboratory. In fact, serologists themselves have found it necessary to caution against the absolute acceptance of the Wassermann test by qualifying it merely as one of the clinical symptoms of syphilis. A negative Wassermann is admittedly inconclusive and can be found in clinically active and well marked cases. Positive Wasserman does mean syphilis but, obviously, does not necessarily mean that the present skin lesions are of a specific nature, for the simple reason that a syphilitic is not only not immune against other skin diseases, but is in fact, more predisposed to them than an average individual.

The Wassermann test has an absolute value in the cases of visceral and cerebrospinal syphilis, and equally so in the therapeutic control of cases of syphilis. In the presence of skin lesions the Wassermann test should be interpreted only in conjunction with these lesions, and in the case of a negative Wassermann the clinical evidence should be given precedence.

Tuberculosis Syndrome.—Another cutaneous syndrome of great clinical importance, tuberculosis, is still less appreciated by the general profession. Besides skin tuberculosis proper, represented by lupus vulgaris and ulcerating and verrucous types of tuberculosis, there is a large number of so-called tuberculides due to the hematogenously deposited bacilli or their toxins. Here belong scrofuloderma, folliculitis, acne varioliformis, lichen scrofulosorum, and erythema induratum or Bazin's disease. All these manifold lesions of tuberculides are, unquestionably, more frequent than recorded in the literature. But due to their insignificant clinical appearance, sluggish chronic course, and the lack of a subjective course they are, as a rule, overlooked and ignored. Yet their clinical significance is much more definite and conclusive than that of the tuberculin test, the diagnostic value of which decreases with the age of the patient. The presence of tuberculides always points to the active or semilatent focal tuberculous infection somewhere in the system, most likely in the lymphatic glands.

Diabetic Syndrome.—Another valuable syndrome offered to the internist is diabetes. A dry lusterless skin, local or generalized pruritus, eczema of the genitals, attacks of furunculosis or carbuncles, dry gangrenous ulcers, and exanthomatous formations—all these symptoms, singly or combined, should suggest an underlying glycosuria. In fact, it is not of rare occurrence that the dermatologist is the first man to detect a latent diabetes on the strength of some of these symptoms.

Erythema Multiforme Group and Focal Infection.—A cutaneous syndrome which should be of intense interest to the internist and still more to the pediatrician is the group of erythema multiforme because of its clinical relationship to the so-called rheumatic infection.

Three types of the erythema multiforme group are particularly often associated with constitutional symptoms of malaise, fever, and involvement of the joints; erythema multiforme of large papular type, erythema nodosum, and the purpuric type, which according to the intensity of constitutional symptoms is termed purpura rheumatica, purpura hemorrhagica Werlhofii, and Henoch's purpura. The early recognition and correct interpretation of these lesions, when they precede visceral symptoms, can be of the greatest service in the prevention of further development of the rheumatic infection and its cardiac complications. This syndrome should be gravely regarded, as a surface indication of deep streptococcic focal infection somewhere in the system, calling for a thorough search, and it should not be lightly dismissed, as is often done.

The group of erythema multiforme is the main representative of dermatoses due to focal infection. However, many other types of dermatoses may be the result of focal infection. Most common clinical types of this character are: erythema-

tous, bullous, herpetic, less frequently eczematous and psoriaform.

Leukemic Syndrome.—Quite recently there has been introduced a leukemic syndrome. It includes besides bluish tumors, which are true granulomata, also persistent pruritus, prurigo-like rashes, bronze-like pigmentations, and purpuric lesions. The appearance and persistent development of these lesions without any definite etiological factor suggests a possibility of latent leukemia or Hodgkin's disease and calls for a blood examination.

Precancerous Dermatoses.—Among dermatoses of vast clinical importance must be included the group of precancerous dermatoses. The importance of skin cancer in the general cancer problem and its quota in the general cancer mortality is, surely, not insignificant. Here belong: seborrheic warts, senile and arsenical keratoses, Paget's disease, leucoplakia, and pigmented melanotic nevi. Each of these lesions is a potential source of malignancy and should be thoroughly removed by cauterization or excision. Every destructive and metastasizing carcinoma starting from the skin has been at some time one of these insignificant and harmless looking seborrheic warts or keratoses. The early recognition and prompt destruction of these precancerous lesions would seem to be a self-evident indication; yet thousands upon thousands of people are walking around with these keratoses without the slightest attention on the part of their medical attendants.

Endocrinous Syndromes.—Possibly the most interesting and promising, from a therapeutic point of view, are cutaneous syndromes based on the deficiency and disorders of internal secretions. The best defined syndromes have been developed about the thyroid gland, which is considered the keystone of the whole endocrinous system.

Between the two extreme types of thyroid dysfunction represented by Graves' disease, *i.e.* hyperthyroidism on the one hand, and by myxedema, *i.e.* hypothyroidism on the other, there is a great number of cases of various grades of intensity of glandular dysfunction. Dermatologically hypothyroid cases are more frequent and are more amenable to therapeutic control.

The hypothyroid skin syndrome is manifested by thick, dry, pasty skin, suppression of perspiration, lusterless brittle hair, and alopecia. Many cases of dry chronic eczema, psoriasis, ichthyosis and scleroderma have hypothyroidism as the underlying etiological factor, and they readily improve from the administration of thyroid.

Hyperthyroidism on the other hand produces thin, perspiring, easily flushed skin, urticarial attacks, pigmentations, distrophies of the nails, keratinization and pruritus. The relationship of other ductless glands and their internal secretions to skin disorders is not as definitely established, yet a number of clinical observations is recorded to substantiate such relationship.

The association of pathological changes in the adrenal glands with the Addison bronze-like skin discoloration and purpuric rashes, as well as the successful treatment of some cases of vitiligo with an extract of suprarenal glands is well known.

The disorders of the hypophysis gland are manifested by a symptom complex of acromegaly, fibromatous growths, warts, alopecia in men and hypertrichosis in women.

Sex Glands.—To the internal secretions of the sex glands are attributed manifold cutaneous disorders; such are, skin changes after castration, herpes progenitalis, erythema multiforme, urticarias, vicarious hemorrhages under the skin and the nails associated with the disturbances of menstruation, types of eruption described under the name of dermatitis dysmenorrhoica—pigmentation of the linea alba and the nipple, chloasma uterinum, and impetigo herpetiformis occurring in pregnancy, and a tendencny to hypertrichosis and acne rosacea in the climacteric period.

The frequent observance of disorders of internal secretions in a very large clinical group of angioneurotic dermatoses such as Raynaud's local asphyxia, symmetrical gangrene, sclerodermia, angioneurotic edema, herpes, and dermographia, is highly suggestive of the close association and correlation of the sympathetic vasomotor nervous apparatus and of the ductless glands.

Anaphylactic Dermatoses.—One of the latest deductive principles accepted by dermatology is anaphylaxis. Its practical application in the form of food protein tests by intracutaneous and subcutaneous methods has for its purpose first to identify the protein responsible for the anaphylactic symptoms and then to effect the desensitization to this substance by injecting gradually increasing doses of it.

I have no experience with the desensitization procedure, but I have used food protein tests in a number of cases for diagnostic purposes and have found them extremely serviceable for the isolation of the offending proteins. They simplify the dietetic control of anaphylactic dermatoses and put it on a definite and rational base. As a whole, the method is too young to admit of tangible results.

Conclusions.—This concludes the presentation of the most important and the best defined syndromes and principles which modern dermatology offers to the internist for clinical utilization. Taking full advantage of these offerings would, no doubt, not only increase the efficiency of the general practitioner in handling skin cases, but to an equal degree would broaden his clinical insight and understanding as an internist. To derive maximum benefit from the dermatological research the internist must revise his old-time conception of dermatology, as a peculiar and detached branch of medicine, devoted largely to a hair-splitting morphological differentiation and to local medication. Dermatology has passed the morphological and pathological stages of its development and now it has entered the final and most productive stage, namely, the biological. The best research of this period centers its attention on the problems of coordination of cutaneous symptoms with the visceral, and on the interpretation of morphological differences in terms of systemic pathology. Obviously, the best results in this field can be obtained only by cooperation of the internist and dermatologist. At present an incredible amount of dermatological material in general practice goes to waste ignored, overlooked, misinterpreted, and unrecorded. On the other hand a large number of cases in dermato-

logical practice in the absence of a thorough systemic examination receive only symptomatic relief, the cases remaining understudied and only partially understood. Dermatological research will not reach its full fruition and will not render its fullest service to the internist until it enjoys the closest cooperation and interchange of clinical observations with general medicine.

TREATMENT OF SPLANCHNIC RELAXATION BY ELECTRICAL CURRENTS.*

By WILLIAM MARTIN, M.D.,

ATLANTIC CITY, N. J.

PRESIDENT AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

In the treatment of any condition, it is a logical thing to consider the pathology and etiology before attempting to outline the therapy, and as a general thing most abnormalities are so treated. The above condition offers no exception to this rule.

Splanchnic relaxation has been variously termed splanchnic neurasthenia, splanchnoptosis, gastroenteroptosis, and intestinal stasis, all of which are descriptive of a part of the underlying conditions. The best known, splanchnic neurasthenia, is perhaps quite a little more suggestive of the symptomatology, but the word "neurasthenia" means so little in this day, that it would seem best to drop it. Relaxation or insufficiency would appear to express more properly the underlying conditions, and therefore might be better terms to use.

The splanchnic circulation is made up of the portal vein and its branches together with the arterial branches of the celiac axis. Of this the liver and spleen contain the larger amount of blood, the liver alone receiving about one-quarter of the whole body's circulation. The splanchnic vessels are capable of containing the whole amount of the body's blood, which demonstrates the possibilities of a profound state of relaxation.

Normally, when one stands erect, the splanchnic vasomotor mechanism causes a constriction of the vessels, which results in an elevation of the blood pressure. When there is a loss of tone of this nerve mechanism, the reverse will be true, a dilatation of the vessels will be the result, and an engorgement of the organs will ensue. In the course of time, repeated engorgements of the liver, spleen, and other organs will assume the pathological type. Normally also the process of digestion adds to the engorgement of the digestive tract, and the liver plays its part in this. This engorgement is physiological and gradually disappears as the digestive process is finished. When, however, there is already a pathological engorgement established, this increases materially at each ingestion of food, which the patient notices and speaks of as an added discomfort to what has already been felt.

Of the nerve supply, the splanchnic is the largest and most important of the vasomotors of that region. Its fibers arise from the 5th to 12th dorsals inclusive, which corresponds to the intervertebral interspaces of the 2d to 8th dorsals. It descends obliquely inward in front of the bodies of the vertebræ along the posterior mediastinum, perforates the crus of the diaphragm, and terminates in the semilunar ganglion, distributing filaments to the renal plexus and suprarenal gland. The great splanchnic nerve of both sides is received into the solar plexus and the ganglia, as are the lesser splanchnics and the right pneumogastric, and this plexus and ganglia supply all of the abdominal viscera. The great nerve supply, both of the vasomotor and sympathetic systems, affords an easy explanation of the difficulties that may arise from an undue amount of irritation of these nerves. We may also have referred pains in the abdomen from irritation of the nerves at some distal part, as will be shown by some excitation of the right pneumogastric being referred to its terminal in the abdomen. Irritation of the communicating branches between the 11th dorsal and the 2d lumbar, causes marked dilatation following a primary contraction, as is the case with irritation of the vagus as noted above. This irritation long continued, finally causes an exhaustion of the nerve energy, and gives rise to a chronic dilatation of the vessel walls, amounting to a practical paralysis. (Landois' "Physiology.")

What part constipation plays in the pathology of this condition may be suggested by the absorption of the bacterial products of the intestinal tract. Autointoxication is the term used in earlier years, but at present writing is not held in favor by some. According to Adami and McCrae ("Pathology," p. 106), that while indol introduced into the tissues sets up headaches, muscular weakness, and a sense of fatigue, conditions resembling those ascribed to constipation, there is not the slightest evidence that indol is produced either from the tissue cells, or even by the digestive juices: It is a tryptophane derivative, a product of protein disintegration. It is formed by the proteolytic activities of the colon bacillus, and along with cresol and the etherial sulphates, is absorbed, more particularly in obstruction of the upper part of the small intestine, being discharged into the urine as indican.

The fact that so many of these patients have ptotses with kinks, acting as obstructions to the fecal current in the small intestine, accounts for the almost universal finding of indican in the urine of these cases. There is also another probable factor involved in the pathology. This is a perversion of the internal secretions of the tract. Since modern advances made in the study of endocrinology, we find these problems coming more and more to the front for solution, but we are not as yet in the position to lay claim to any great certainty of knowledge. Just what part secretin plays in these cases has not been determined. We know from experiments that it stimulates the flow of pancreatic juice, as also does the secretion of the pyloric glands stimulate certain glands in the cardiac portion of the stomach.

No doubt we will learn in time just where and how these hormones are influenced by the various electrical currents when applied for the correction of these abdominal conditions, which will scientifically and satisfactorily explain the excellent clinical results of treatment.

The symptomatology of splanchnic relaxation is

*Read before the Medical Society of the District of Columbia, Washington, D. C., Jan. 14, 1920 (by invitation).

suggested by the pathology. Added to the symptoms enumerated earlier in the paper, we have insomnia as a prominent one. Nervous excitability is also featured, and mental depression follows soon in its wake. This may become a full-fledged melancholia in time, and may be termed pathognomonic of the advanced stage. Some of the minor features are digestive disturbances, dizziness, tinnitus aurium, migraine, flatulence, and abdominal pains. Many speak of a sense of weight in the lower abdomen, a dragging down that is most uncomfortable. This may be accounted for by the actual sagging of the abdominal organs, with the body's posture changed to meet it, together with the actual nerve disturbance incident to this.

In determining this condition of relaxation, it is necessary to make some physical examination with the clothing removed from the abdomen. The patient, standing, shows the sagging, and palpation will demonstrate the change of position of the organs. In the recumbent position, normally the abdomen drops moderately below the rib line, while in this condition it rounds out more or less prominently, according to the particular case. Here again palpation will elicit points of tenderness, faulty position of the organs, and a tenseness of the abdomen, which may be in part due to flatulence, but in some largely due to the liver engorgement.

It is not the purpose to enter into a discussion of the diagnosis further than to mention a prominent factor that is quite constant. This is the disparity of the blood pressure findings in these cases, and this is pathognomonic. The same applies to the pulse findings. It may be mentioned simply by stating that as a rule the pressure is of the hypotension type, irregular in the arms, and higher lying down than sitting. The pulse as a rule is more rapid in the recumbent posture, thus reversing the rule.

Treatment of splanchnic relaxation resolves itself empirically into three subdivisions: hygienic, including diet; electrical or physical measures, and mechanical, including exercises of recognized types.

Proper living will do much toward prevention of the later stage when undertaken early enough. Dietary care in the line of cutting down of proteins, or in many cases the total elimination of these, will produce favorable results. This will be evidenced by the lessening and disappearance of the indican in the urine, as well as by a sense of betterment felt by the patient. They all do well under the vegetable and fruit diet, with some fats, such as olive oil, butter, and perhaps bacon. Cereals may be used in cases where they agree, or where the patient is not afraid of adding to the adipose. All need to keep the system flushed with plenty of water, and in the cases of hypotension large amount may be taken to advantage.

The bowel must be kept free from accumulations. A dose of castor oil once in two weeks is a good rule. During the early stages of treatment, owing to the intestinal stasis, a mild laxative may be given as needed, but it is advisable to leave these drugs off just as soon as possible. Mineral oil or agar may be given with safety, as they are not drugs and are not absorbed into the system. As these patients are easily influenced psychically, it is best to dwell as little as possible upon this feature of the trouble, as many get obsessed with the idea that the bowels must be frequently moved, and are not satisfied by the ordinary regular actions.

Rest before meals will be advisable in the average case, particularly before the noonday meal. Fifteen or thirty minutes in the recumbent position before eating will do much to restore tone to the digestive organs. Some are benefited by a similar rest after the hearty meal. Each case must be advised according to its merits.

Exercise in the open air and sunshine is a very important part of the treatment. At first the sense of fatigue will make it difficult to get the cooperation of the patient in this matter, but a carefully given outline of what is to be done will be more sure of getting the patient to follow out the directions. It is best to start with short walks which can be gradually increased until a sufficient distance is walked daily. The patient's interest will be aroused in this way and cooperation secured. Always advise against getting overtired.

As insomnia is one of the prominent symptoms, and one that causes great anxiety on the part of the patient, his fears may be largely removed by the statement that resting quietly in bed two or three hours will represent at least one hour of sleep. As under the treatment insomnia usually leaves early, it is advisable not to use drugs for producing sleep, assuring the patient that these simply put off the evil day and do no permanent good, and by not using them the chances are far more favorable for results to be had early. In the writer's experience, the patients have slept fairly well after a few treatments, and normally after a couple of weeks, and soporifics have never been used.

The actual treatment of these cases by electrical currents will be outlined by what the writer does in the average case, but it will be recognized that individual cases may require variations from this. It may be good policy to take up each part in detail, as some may not be conversant with the methods used, and may not fully understand unless the technique is given.

The first thing to do is to apply the high frequency current to the liver and splanchnic area by the diathermic method. To do this, a machine that will deliver the D'Arsonval current is essential, as this is the current of greatest amperage and lowest voltage, which means the greatest amount of heat will be supplied to the tissues through which it passes, and at the same time produce the least disturbing effects.

The electrodes used are made of flexible metal, usually lead and zinc, which can be cut and fitted to any part of the body with ease. Their size should be approximately 3 x 5 inches for every 1,000 milliamperes of current. The electrodes may be differently shaped, but the relative proportion should be kept so far as is possible in order to secure the best effects. In applying the electrodes care must be used in the actual fitting of the anterior one, as the ribs will in a measure prevent accurate approximation. The posterior electrode will offer no difficulty as the back is easily fitted. The electrode should be moistened and, in some cases where the skin is dry, it should be well dampened

also, otherwise sparking between the metal and the skin will take place and a burn be produced. These burns are slow to heal and offer difficulties to further treatments.

The electrodes are usually held in place by the patient, using the body weight for the posterior and the hand or hands for the one in front. Turkish towels are used over each to absorb the excess moisture and to make it possible to hold the metal plate. By the use of these towels the writer feels that scalds are prevented, as excess moisture may be quickly turned to steam by the intense heat of the current, which will be prevented by this method. Another point to be observed is that the electrodes should be as nearly opposite each other as is possible for an even distribution of the current. The tendency of electrical currents to go by way of least resistance will be shown by its accumulation at the end of the electrodes that happen to have the least distance between them, so if the metal plates are so placed that the two ends are too near the curve of the body, the current strength will accumulate there, and the chances are that a burn will follow, or the patient will complain of too much heat, so that the current will have to be reduced in strength, to the patient's disadvantage.

The length of treatment varies with the case, the large-bodied patient requiring a longer time, as a rule. The average time is twenty minutes, but thirty may be given to advantage at times. The amount of current also varies, but the average is from 800 to 1,200 milliamperes. It is the writer's practice to use moderate amperage rather than the larger, unless local elimination is essential or there is considerable pain to be relieved.

The effect of this treatment will be seen by a gradual lessening of the liver engorgement and better bowel activity, no doubt because of an improved condition of the intestinal secretions.

The next step is the application of the sinusoidal current. This may be given by the use of either of two types of apparatus, galvanic or faradic. The writer for some years used only the galvanic type with splendid results, but of recent years more use has been made of the faradic type. In the latter the use of different shaped cams make it possible to give the current with many variations that appear to be beneficial. By this we secure deeper effects and the long and short effects alternating, as one chooses, according to the individual needs. It is well to have both types in the office, so that one may be able to select the best for each case that presents.

The electrodes used for this treatment are pads made of metal covered with asbestos and gauze, the latter sufficiently thick to hold moisture well. Each pad should have a metal plate on the upper side for making the proper connection with the cord attached to the machine. These pads are available in the market made much better than one can make them in the office.

These should be sterilized by boiling, preferably, and the sterilizer can be used to keep them warm, as warm electrodes carry the current better and are more comfortable to the patient. It will be observed that they are applied wet, and, in fact, the writer applies them as wet as is conformable with comfort to the patient, using the turkish towels to absorb the excess and to protect the clothing. In the sinusoidal current there is no polarity, or rather the polarity changes with each wave, so it matters little about placing the pads from this standpoint. It is usual to apply the smaller as the active one over the spinal area, and the larger over the abdomen. The spinal pad should be wide enough to cover the skin at least an inch each side of the spinal column, and long enough to cover the intervertebral spaces of the nerves involved.

The usual size is 4 x 6 over the spine, or a longer one if preferred, with either a pad 8 x 10 or 10 x 12, as one may choose for the abdominal application. This latter pad may be applied directly over the center of the abdomen, or it may be placed over the ascending colon for a part of the time and then over the descending colon. The treatment time is usually twenty minutes, and the strength of current measured according to the patient's tolerance, as few, if any, of these machines have a meter in circuit for measuring the current strength. No doubt the machines of the future will have to make this change to meet the needs more accurately.

Another method approved by some is that by the use of bipolar electrode. This is made up of two small pads upon a frame that allows of adjustment for width. This is strapped to the body with a pad on each side of the spine just below the inferior angle of the scapula. In this type there is no need of the abdominal pad. The one objection to this is that the patient must sit up in a chair instead of lying down, and as a rule the patient is more comfortable in the recumbent position. The rates of sines should be about twelve to the minute in either type of treatment.

In this treatment, the pads being very wet, the turkish towels come in play again to protect the clothing of the patient. The tonic effect upon the nerves and musculature is quite pronounced, and peristalsis being activated, insures a better state of the bowels.

As a final step in the treatment, vibration is essential. Remembering the nerve distribution, we vibrate the interspaces of the 2d to 8th dorsal vertebræ for two minutes, for its stimulating effect. In some cases the heart muscle tone is below par, in which case we vibrate the interspace of the 7th cervical and 1st dorsal for two minutes.

The writer cannot too strongly condemn the practice of some who vibrate the whole spinal column, as it is not at all scientific and does not meet the requirements and in some cases may do actual harm. To be of real value, vibration should be scientifically applied, and one should be conversant with the nerve distribution.

In some advanced cases of ptoses the mechanical supports may be of distinct value, particularly during the early part of the treatment. These belts or pad supports not only support the abdominal walls, but they increase the intraabdominal pressure which is lacking in all of these cases. They should be accurately fitted and only worn for a time until the muscle strength is restored by proper exercises and other means. In applying these the patient should be in the recumbent position with the hips higher than the trunk so as to allow gravity to carry up the organs. The same applies to the corsets of the ladies, which may be laced

tighter when standing. These corsets should be of the front lace kind, long in front, fitted by measurement, and laced from below upward, which will make them more or less loose at the top.

Exercises were just mentioned as being of value. This is recognized by the profession generally, and all know just what are needed, so it will not be necessary to go into detail about them. The kind most needed are those that bring the abdominal and back muscles most actively into play. One thing must be borne in mind: Never tire out the muscles in this effort to build up. It will be far better to gradually work up to a more full system of exercises than to undertake to do a number at one time. Correction of posture is of great importance in these cases.

It would seem that the subject is almost interminable, but as the main parts of it have been treated, the writer will desist from further details and in conclusion will simply repeat that in his judgment the important point after all is early recognition of this condition, and with this the rest is easy, and he trusts that this poor effort will inspire you with a more keen desire to do all that is in your power for these sufferers.

Maryland and Pacific Avenues.

ACUTE INTUSSUSCEPTION;

REPORT OF A CASE RELIEVED BY ENEMA.*

By SAMUEL K. LEVY, M.D.,

Brooklyn, N. Y.

Clinical Assistant on Surgical O. P. D. of Brooklyn Hospital, and on Pediatric O. P. D. Jewish Hospital.

One is greatly surprised in reviewing the recent literature on this subject, to note how few references there are to this mode of treatment; while, by contrast, many reports similar to this one can be found in the medical literature of five years or more ago.

The case here reported was a typical case of intussusception clinically, and most authors agree that there is a very typical picture of this condition.

There are many who claim that when these symptoms are manifest, immediate operation should be resorted to. It is to suggest the *utility of giving less radical methods at least a hasty trial, especially in those cases seen early*, that I desire to report this case.

Not all pediatricians and surgeons are in favor of immediate operation, and there are those who advise the use of manual and aerohydrostatic methods, even in long-standing cases. Notable in this group are several Danish clinicians.[1] Porter[2] advocates this method, yet sees "no good reason why the abdomen should not be opened and a similar procedure be undertaken in full view of the surgeon." Hess,[3] in a very interesting review of this subject, says, "It is before decided pathological changes in the intestine will have taken place that we may hope to obtain results by irrigation, or other mechanical methods of reduction." Griffith[4] advises the use of non-surgical methods of reduction in cases that have lasted only one or two days. McMurtry[5] cites a case of nonoperative reduction after three days duration. Apfel[6] gives a little review of the literature and mentions Kerley's case of reduction of an intussusception, which had existed six days, by means of water pressure. Dawe[7] reports a case of acute intussusception reduced by manual manipulation over the abdomen, together with enema.

So I could mention numerous other cases of successful reduction by nonoperative methods, especially as recorded in the older literature.

It is only proper to state that even in my cursory review of the literature I found reports of cases of fatal termination after resorting to these aerohydrostatic methods of reduction, as due to causes other than the delay in operation. Fenwick[8] reports the use of enemata in a case of intussusception causing rupture of an ulcer in the transverse colon.

I might also mention that several cases of spontaneous cure of intussusception are reported. Usually the parts involved sloughed and were passed off in the stool.

The etiology, in these cases, is often very difficult to determine. All agree that the condition is most frequently seen in robust infants, between the ages of six and sixteen months.

Cubbins[9] reports several cases in which he found a long mesentery as the anatomical pathology. However, it seems that some contributory or exciting cause must be present, in addition. Tumors of various sorts, intestinal worms, persistent constipation, medication, and other widely dissociated causes are mentioned. Hess[3] in his collection of 1028 cases with statistics, discusses this phase of the subject more in detail.

Grace A., age 7 months, breast fed. Seen at 2 P. M., December 3, 1919, when her mother gave the following history:

Chief Complaint.—Vomiting yellowish fluid material since about 10 A. M. with absolute refusal of all food. Also intermittent attacks of severe griping abdominal pain, coming at irregular intervals, causing rigidity of the entire body; with this the child would scream, because of the pain. These attacks lasted but two or three minutes, leaving intervals when she would go to sleep, apparently exhausted, especially towards the latter part of the morning. The child had passed two normal stools early that morning.

Family History.—Mother well. Father now suffering with pulmonary and renal tuberculosis. The baby's von Pirquet reaction was negative.

Past History.—The only thing suggestive of an etiology was a slight constipation, which the infant had been having for the past week, having but one rather hard movement per day. The mother said the child weighed almost 18 pounds one week previous.

Physical Examination.—A robust child, extremely pale, apparently in severe pain, and in fear of my approach. The abdomen was slightly distended, but soft, with no rigidity or muscle spasm. There appeared to be generalized tenderness, but I was unable to palpate any masses. I did not, at this time, make a rectal examination. The temperature, by rectum, was 98.6°. The child's skin was clear. Throat and ears negative, as was also the chest. All reflexes were active and there was no neck rigidity.

Immediately after this examination the child vomited a yellowish clear fluid.

I advised the mother to put the child to the breast every four hours for but five minutes at a time, to give plenty of boiled water, and to apply dry heat to the abdomen.

At about 7 P. M. the same day, I was again asked to see the baby, because it had had an evacuation of blood from the rectum a few minutes before. I learned that the vomiting and attacks of pain had continued much as before.

*Read before the Clinical Conference of the Surgical A service of the Brooklyn Hospital, January 10, 1920.

The infant showed the same extreme pallor and fear of all who approached. The abdomen remained slightly distended but soft, and I could palpate a small, firm, oval mass about the size of a walnut, in the left lower quadrant just to the left of the midline. During this examination the child had another mucosanguineous stool. By rectal examination I was just able to touch a smooth mass high up and to the left.

I then had about a quart of sterile water placed in a syringe suspended about 4 feet above the level of the child. The child was placed horizontally on her back and a copious quantity of water was allowed to flow into the bowel, while I held the anal tissue firmly about the rubber tip for about a minute, to prevent its escape. Bloody fluid was then allowed to escape, and more sterile water was injected. This procedure was repeated until we had used almost the entire quart of solution. With the escape of the last fluid, I believe, and this belief was confirmed by all those who were about, some flatus was expelled. However, the amount was only small and I thought it advisable to send the child to the hospital at once. Before sending her I made an abdominal examination only, and was then unable to feel any mass.

After the enema, the mother says, the child seemed greatly improved throughout the time she was able to observe it. At the Brooklyn Hospital my diagnosis was confirmed. Abdominal and rectal examinations here proved negative. Another enema was given with bloody fluid return. It was decided not to operate at once, but merely to observe, for the child was greatly improved. It did not vomit, nor pass another bloody stool (voluntarily) after the enema that was given at home, and remained apparently free from attacks of abdominal cramps. The following day another enema was given with the same mucosanguineous return but no feces. However, on the day after this the child had a normal fecal movement. The child received albumin water the first night after admission but the following day was placed on 4-hourly breast feedings. She was detained at the hospital till all occult blood had disappeared from the stool (a period of one week) and then discharged cured. Her stay in the hospital was afebrile.

Her weight on discharge was 15 pounds, 10 ounces. Several months have since elapsed, and she has had no symptoms of a recurrence.

Various heights are recommended for the elevation of the enema container, but after reviewing the literature, I conclude that it is not advisable, under any circumstances, to have a greater elevation than 6 feet.

Pynchon, quoted by Reeves,[10] says, "The fall of water may vary from 15 to 30 feet, according to the age of the patient, and the stages of the trouble, providing that a lesser fall of, say, 6 feet, in alternation with massage, is not successful." Reeves emphasizes the importance of intestinal irrigation in the treatment of intestinal obstruction but advises against the use of such great pressures and mentions experiments upon animals where fluid was forced from the anus through the mouth.

AN UNUSUAL CASE OF DELAYED POSTOPERATIVE HEMORRHAGE FOLLOWING TONSIL AND ADENOID REMOVAL.

By ERNEST V. HUBBARD, M.D.,

NEW YORK.

ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

When the Mackenzie and the Mathieu tonsillotomes were the customary instruments for tonsil operations, with removal of adenoids, postoperative hemorrhages from tonsil crypts and stumps were of frequent occurrence. With the advent of the various forms of cold wire snare these hemorrhages became less frequent. Following the substitution of the Sluder operation where practicable, the number of patients having postoperative hemorrhage has still further decreased. In a very great majority of cases such hemorrhages come from the tonsil area. To find bleeding from the nasopharynx in the adenoid region, commencing again after twenty-four hours following the operation, is comparatively uncommon.

The following history shows the need for keeping in mind the possibility of *late* nasopharnyngeal hemorrhage:—

A girl, 8 years old, had negative family history. Personal history included ordinary ailments of childhood with no complications. No family or personal history of hemophilia. Patient suffered from frequent head colds, recurring attacks of tonsillitis, and the usual symptoms of adenoids. Examination of the throat showed submerged tonsils with a small amount of pus on the surface. There were no ear symptoms. Local treatment gave only temporary relief, the attacks of tonsillitis recurring. Several separate lymphatic glands of the anterior cervical chain were beginning to enlarge. Operation was advised. Under general (ether) anesthesia both tonsils were removed by the Sluder method, and adenoids with the Brandegee forceps and curette. There was only a moderate amount of adenoid tissue. During the operation, and subsequently, there was rather less than the usual amount of bleeding. The patient left the hospital, with uneventful recovery, at the end of two days.

Inspection of the throat a few days later showed healing of tonsil areas. No adenoid tissue remained in the nasopharynx, and nasal breathing had become entirely unobstructed. The patient returned to her home, out of town.

The tenth night after the operation, the child meanwhile having progressed normally, a profuse gush of blood from the mouth and nose wakened her from sleep. The hemorrhage continued and a large quantity of blood was lost. Applications of ice, peroxide of hydrogen, and adrenalin failing to check the hemorrhage, Dr. E. P. Whelan of Nutley, N. J., was called, and introduced a posterior nasal plug. The patient was almost pulseless, but retained consciousness. An intravenous saline infusion, 250 c.c., was given. On arriving, two hours later, I found her improving. The hemorrhage and air hunger had ceased. The pulse was 160, temperature (rectal) 100° F.

Half a pint of saline solution was introduced into the rectum and retained. Strychnine sulphate, 1/60 of a grain, was given hypodermatically every four hours. Improvement continued.

The following evening the nasal plug was removed and the strychnine discontinued. Calcium lactate, 15 grains, at four hour intervals, was ordered. A careful inspection of the throat showed no change in the tonsil areas. They appeared entirely healed and normal. The bleeding had been wholly from the nasopharynx.

Subsequent history is negative, there being no further hemorrhage, and the patient slowly recovering.

As I have said, the case illustrates the possibility of a *late* nasopharyngeal hemorrhage following adenoid removal.

17 East Thirty-eighth Street.

Medicolegal Notes.

Verdict of Coroner's Jury Held Not Admissible in Evidence to Fix Liability in Civil Suits.—Overruling many of its previous decisions on the subject in similar cases, the Illinois Supreme Court holds that a coroner's verdict as to the cause of the death of a servant is not competent evidence in a proceeding under the Workmen's Compensation Act, since the employer is not a party to the coroner's investigation, nor is the coroner a judicial officer. The court is of the opinion that it should no longer be the policy of the State and the holding of the court that a coroner's verdict or inquest should be admissible as evidence in civil suits for the purpose of establishing personal liability against any individual in cases where the death of any person is charged or to establish a defense to such a suit, or for the purpose of establishing other issues between private litigants. The court says that a review of the earlier cases in which it took the opposite course, and admitted such evidence, discloses the fact that many, if not all of these cases have been largely controlled by the admission in evidence of the verdicts of the coroner's jury, and in many of them such verdicts have furnished the sole evidence to establish liability.

As a consequence of such practice there has resulted in the State of Illinois a race and scramble by litigants to secure a favorable coroner's verdict that would influence or control in case a civil suit should be brought to establish a claim by reason of death. It was not intimated by the court that plaintiffs prosecuting such suits have offended more in this particular practice than defendants who are sued in such suits, and it was believed that the facts would disclose that both are alike guilty. It cannot be questioned, the court added, that as a result of such practice the coroner's verdict in many cases has been and will continue to be a mere trap or device for the purpose of catching the unwary in such suits, and that public interests intended to be served by coroner's inquests may not be so well guarded as they otherwise would be. So far as the court had made investigation, only two other States in this country, Iowa and Mississippi, have adopted the same view as the Illinois court formerly did with reference to the admissibility of the inquest of the coroner's jury as evidence in such cases. In the Iowa cases dealing with the point the admissibility of the verdict or inquest was not questioned by the parties. In one of these cases, Tomlinson v. Sovereign Camp, 100 Iowa 472, the court indicates that it might have ruled otherwise if objections to the evidence had been raised. The decided weight of the authorities in this country is against the admissibility of such a verdict as evidence. The court cited in support of this statement cases decided in Kentucky, Maryland, Pennsylvania, Alabama, Wisconsin, Michigan, Oregon, Washington, California, South Dakota, Nebraska and Texas.—Spiegel's H. F. Co. v. Industrial Commission (Ill.) 123 N. E. 606.

State Statute as to Providing and Furnishing Narcotics by Physicians.—The Minnesota statute, chapter 260, laws 1915, section 1, forbids the sale of narcotic drugs, but provides that pharmacists may dispense them upon the written prescription of a physician, and that a physician may administer such drug to a patient upon whom he is in professional attendance. There are exacting requirements as to records to be kept in both cases. Section 2 forbids any physician to furnish or prescribe any such drugs for the use of a habitual user, provided this shall not prevent a physician from prescribing in good faith for the use of any patient for treatment of the drug habit such substances as he may deem necessary. The Minnesota Supreme Court holds that it was proper, in proceedings for violation of the act, to instruct the jury that the statute makes a distinction between the dispensation of these drugs to habitual users and to ordinary patients, that in the case of patients not addicted the physician may prescribe them and also furnish them, but that in case of habitual users he may not furnish the drug, but may only give a prescription to be filled by a pharmacist under the safeguards imposed by the law. It was held proper to receive evidence of other sales of narcotics to the same addicts and of sales to other addicts. Such evidence was held within the rule which permits evidence of this character when it is part of one scheme to violate the law or when it tends to show an inclination or predisposition to violate the law. The trial court was not in error in refusing to receive in evidence a stamp with which the defendant said he stamped all containers of such drugs dispensed by him. A package found on the person to whom it was charged the defendant sold morphine bore no stamp, but it was admitted that the defendant furnished him the quantity of the drug found in his possession.—State v. Whipple (Minn.) 173 N. W. 801.

Privileged Communications—Waiver—Conversations After Relations Have Ceased.—In an action for injuries to a pedestrian, run over by a street car, the defendant examined Dr. S. as a witness. Dr. S. aided Dr. B. in the treatment of the plaintiff at the hospital immediately after the injury. The defendant asked the witness certain questions as to what the plaintiff had told him as to the circumstances of the accident. This line of examination was objected to on the ground of privilege under the statute, Dr. S. being deemed to occupy at the time the relation of physician to the plaintiff as his patient. The Iowa Supreme Court held the objection was properly sustained. The privilege was not waived by the plaintiff by his testimony on cross-examination. Testimony thus given by the plaintiff on cross-examination is not deemed voluntary, and is therefore not a waiver. Thereupon inquiry was made of the witness as to conversation had with the plaintiff after the profession relation had ceased. Objection was made to this line of examination on the same ground as before and sustained. It was held that this objection should not have been sustained. The defendant had a right to inquire into conversations had after the termination of the professional relation. These in the statutory sense were not confidential.—Arnold v. Ft. Dodge D. M. & S. R. Co. (Iowa), 173 N. W. 252.

Contributory Negligence of Patient.—In an action for malpractice for neglect of professional duty in treating a fracture of the plaintiff's right leg, between the knee and the ankle, it appeared that the plaintiff contracted erysipelas, which he alleged was the result of bandaging cloths or bandages and lacing a shoe too tightly upon the limb, and of the failure to properly attend thereto, it was held that under the evidence, which was not detailed in the court's opinion, the question of the defendant's negligence, and of the plaintiff's contributory negligence, were fairly questions for the jury. Even if a physician has been negligent in some respect, it is well settled that the patient must not have contributed to his injury in any degree; that he must conform to all reasonable directions of his physician, otherwise he cannot recover.—Hanson v. Thelan, North Dakota Supreme Court, 173 N. W. 457.

Death from Sunstroke.—The New York Appellate Division holds that an award for an employee's death from sunstroke is not justified where the Industrial Commission does not find that he met his death through exposure to heat more excessive than that to which others were subjected, or through any special hazard of the employment, of track worker on a railway, but merely finds that he met his death from sunstroke arising out of and in the course of employment.—Drezzenski v. Crenshaw Engineering Co., 177 N. Y. Supp. 100.

SECONDARY WOUND CLOSURE.

ONE of the many surgical lessons of the great war came in the results of treatment of certain types of infected wounds. After they had been cleaned up, secondary suture was employed in a large percentage of the cases instead of allowing them to close by the slow process of granulation. This resource should and doubtless will be adopted in civil practice to an ever increasing degree when it becomes generally known how great an economic saving results, not only to the patient but also to the community through the quicker return of the individual to productive activity. During the last year of the war and since its close, numerous text-books on war surgery have devoted sections to methods of preparation for and the technique of delayed primary and secondary suture of wounds; and many statistical tables have been published showing the results of such treatment.

Among these, a report by Brenizer (*Surgery, Gynecology and Obstetrics,* December, 1919) on 961 cases of secondary wound closure is particularly interesting and instructive. These cases were treated at Base Hospital No. 6, A. E. F., France, between April 8 and December 11, 1918, a period of eight months. The greater number of these closures were made on the fourth to sixth day, after the reception of the wound and the primary excision, and before the twelfth day, that is before the thin, bluish, attenuated epithelial edge had formed and the skin had become fixed in its retraction.

Brenizer and his associates first closed a few wounds without bacteriological control and without the removal of the more loosely textured surface granulation tissue with Dakin's solution. They simply painted the surrounding skin and granulation tissue with iodine, dissected the granulation tissue and thin layer of connective tissue from the underlying structures *en masse,* and closed the wound. Most of the wounds healed even in this way, but a few of them became red and swollen, the patient became toxic, and the wound broke down. In these wounds they almost always found the streptococcus. They then disregarded entirely the quantitative bacteriological examination of wounds and depended upon qualitative cultures to eliminate the streptococcus, gas bacillus, and tetanus bacillus. When the streptococcus was found the wound was treated with Dakin's solution by the Carrel method until the streptococcus no longer appeared in cultures. When the gas bacillus was found, the wound was similarly treated and Bull and Prichett's gas bacillus antitoxin was given. When the wound was very moist and covered with necrotic tissue, it was chemically scoured with Dakin's solution.

The technique of secondary closure was carried out as follows: "The surrounding skin was cleaned with ether and painted with iodine and the whole granulating surface was covered with gauze soaked with iodine. A clearcut incision was made just outside the epithelial edge, through the skin, and the skin undermined. The granulating area was then undermined and dissected away *en masse,* thus removing mechanically the bulk of all bacteria. The granulation tissue was not scraped off but was dissected off with a layer of the new-formed connective tissue down to the fresh, bleeding, underlying structures. The raw area was again painted with iodine and all bleeding carefully stopped. Fascial planes were closed, all necessary repair to tendons, nerves, and vessels was done, including curettement of bone, and the skin edges were closed without tension." In this way 961 wounds were closed with but one death, that being from tetanus in a case having received three injections of antitetanic serum, the last less than ten days before the wound closure. Closure was entirely successful in 894 cases, or 93 per cent.; partially successful in 38 cases, or 4 per cent.; and in 29 cases, or 3 per cent., the operation failed.

The cases of open wounds with fracture were selected cases showing little or no comminution and no small fragments. The success with those cases, however, hardly justified continuance of the treatment. The secondary closures of amputation stumps were successful, save for an occasional sacrifice of bone; but secondary suture was abandoned for traction and spontaneous closure in most cases. Brenizer found the most difficult wounds to close were those of the hands and feet, and the wounds everywhere over the body where a circular area of skin had been cut away at the time of primary excision. He found that, eliminating the streptococcus, gas, and tetanus bacillus, wounds of the soft parts may be closed by ordinary surgical technique with as high a percentage of healing *per primam* as by other methods; also that a small dosage of staphylococci or attenuated contamination of the wound by staphylococci, after secondary excision and secondary closure, does not interfere appreciably with the healing of the wound.

Surely, the results in this series of cases form a strong argument for the employment of secondary closure in suitable cases in civil practice.

MYOCLONIC ENCEPHALITIS.

SICARD believes that encephalitis lethargica is a clinical group-affection whatever its nature, which differs with the localization, being expressed respectively as a cortical encephalitis, mesencephalitis, myelitis, etc. He suggests as a comprehensive term epidemic neuraxitis. (*La Presse Médicale*, April 14, 1920, xxviii, 22.) In addition the nerve roots may be involved so that radiculitis results. In the present connection he limits his remarks to the myoclonic type of which he has seen five well defined cases. The first patient showed neither lethargy nor ocular pareses; instead of lethargy there was insomnia. The diagnosis was at first most obscure and among the maladies suggested were tetanus, rabies (history of exposure to a dog), and infectious chorea. The second patient was equally free from somnolence and eye troubles. No diagnosis was made. The third case was very similar to the preceding, but by this time the nature of the malady was strongly suspected. All three patients succumbed. The other two patients recovered.

To sum up briefly the clinical phenomena: the disease began in the midst of perfect health with prostration and lightning pains involving the nerve roots of the cervical and intercostal regions. Fever next developed and was very moderate. Locomotion and even sitting up were impossible. The mind was clear and cerebral symptoms were very vague. A week or ten days passed before further developments. Myoclonus then appeared, often generalized and often most marked in the abdominodiaphragmatic region. After a periad known as status myoclonicus the subject developed delirium of the oniric type and gradually the clonus subsided. Coma followed by death, or recovery ensued. The spinal fluid was practically normal. The condition is clearly not a form of lethargic encephalitis although evidently due to the same cause. It corresponds with the electric chorea of Dubini.

The American Red Cross reports that a similar affection prevails in Vienna where some three hundred cases of what is tentatively called cerebral influenza are being treated in the various hospitals. Of 71 cases treated during April by the Red Cross physicians 40 terminated fatally. The disease ordinarily begins with headache and insomnia followed soon by clonic muscular contraction of the limbs, face, and abdomen. In some cases there is paralysis of the ocular muscles, preventing closure of the eyelids and producing an illusory appearance of insomnia even in patients lying in the profoundest stupor. Fever does not necessarily accompany the malady in the early stages but appears later when the patient passes into violent delirium accompanied by auditory and optical hallucinations. In the worst cases death comes in a few days. Persons between the ages of 18 and 35 are most often attacked. Pregnant women appear to be particularly vulnerable to attack. The disease is not confined to Vienna but is reported to be spreading throughout German Austria.

AMYL NITRITE IN THE PERIPHERAL VASOCONSTRICTION OF THE SHOCKED SUBJECT.

DUCASTAING writes briefly on this subject in *La Presse Médicale* for December 20, 1919, xxvii, 78. The arterial spasm in shock is responsible for part of the disease picture of the latter. Two cases are given, in one of which the subject, an artilleryman, received a severe shell wound, with great exposure of muscle bellies. There was traumatic shock with earthy face, unconsciousness, absence of motor restlessness, and bradycardia, the latter phenomenon being unusual. This state persisted for twelve hours, upon which, under ethyl chloride, the wound was treated heroically by extirpating all devitalized masses. The new surface was irrigated with warm saline and ether, and Carrel irrigation begun. Serum and camphor were injected. Two hours later the patient was still unconscious, still had bradycardia, pupils normally dilated and reacting to light. With the diagnosis of arterial spasm nitrite of amyl was given in inhalation and the pulse mounted to 80 (from 40-45), but soon returned to the low figure. There was absence of many of the active phenomena of shock. As soon as the arterial tension began to increase and the frequency to mount, the state of calm was succeeded by the picture of agitation, subdelirium, nausea, and gastric intolerance. In the second case, which resembled the first save that pulse was quite absent from the radial, nitrite of amyl at once caused the beat to appear at the rate of 130. As in the first case the gradual reaction of the circulation changed the picture from quiet to agitation, leading to a fatal exit. In these cases nitrite of amyl showed that a condition of peripheral vascular spasm was present with a general inhibition of much functional activity. Evidently subsidence of this spasm will alter the picture to one of the opposite type. The condition in the second case was complex, for to the primary wound shock was added operative shock, while in the first patient gas gangrene rapidly developed.

SLOW EVOLUTION OF TYPHOID PERFORATION.

THIS condition can be studied only in cases in which the patient must not be submitted to operative intervention. Gautier and Brutsch relate such a case in the *Revue médicale de la Suisse Romande* for December, 1919, xxxix, 12. The patient, a robust young man, was admitted to the hospital for "fever" which had been coming on insidiously with failure of health. The case proved to be one of walking typhoid with the picture of emaciation, severe headache, diarrhea, and mental torpor. The temperature was above 104° F. An abdominal examination revealed no complications and the stools contained no blood. The pulse and blood count were excellent, as was the state of the urine. There was a positive serum agglutination of Eberth's bacillus. A crisis then took place in which the patient vomited and became tympanitic, while the temperature

fell several degrees. Vomiting continued with hiccup, and the temperature curve underwent an entire change, the patient at times being almost apyretic, while the maximum was not over 102.5° and this for a short time only. There was no abdominal resistance. The patient remained in this condition several days when the diarrhea, which had ceased with the appearance of vomiting, reappeared with blood in the stools, and soon afterward resistance was noted in the abdomen in the hypogastrium, the diagnosis of perforation being now made for the first time. Treatment was strictly expectant and the patient's state was in some respects still good, but the prolonged vomiting had made it impossible to maintain his forces and this fact with the exhausting diarrhea and constant escape of blood led to death. In this case the blood-counts seem to have been very deceptive, there had been at no time more than medium temperature which was gradually falling, while the pulse seems to have been uniformly low and of fairly good tension up to the time that the perforation took place.

The Mental Malady of de Maupassant.

The alienation of this celebrity has been variously interpreted and several years ago a Canadian physician attempted to show that it was due to progressive paralysis of syphilitic origin. Charles Ladame, a Swiss physician, has recently written a monograph on the subject, noticed in *Le Progrès Médical* for February 14, 1920, xlviii, 7. It is admitted that his death was almost universally held to be due to that disease, but for many years he had shown evidences of insanity and this fits with the belief that his trouble began with syphilitic meningoencephalitis which destroys life with relative rapidity. The author was evidently at least markedly psychopathic before the development of the organic malady. This is shown in his writings, while enough is known of his conduct to justify the belief that he had been for many years the victim of a psychosis. The study under review appears to be limited largely to the author's writings rather than to his behavior. The handwriting test shows plainly that he had developed paresis, but if followed back, it also appears that this malady had not been present for longer than a few months. His last work, *l'Angelus*, exists in manuscript and is said to bear no evidence whatever of paresis. The frequently recurring accounts in his works of the phenomena of mental alienation cannot be properly cited as *prima facie* evidence that the writer himself was alienated. The test could be applied to perfectly sound authors with negative results. The ability to visualize morbid minds is an attribute of genius expressed in an instinctive psychology. De Maupassant does not appear to have been a born psychopath as he was a man of vigorous animal health and strength. If his mental troubles were really due to the slow action on the cortex of the spirochete or its products his case is unique, for this agency has never been known to be in any sense a stimulator of mental function, being thus in direct contrast with the toxin of tuberculosis to which such properties have repeatedly been assigned.

News of the Week.

Smallpox at Dvinsk.—Smallpox has broken out in the province of Latvgallia, and unless checked seriously threatens the Baltic States and Poland. The American Red Cross field unit, which was recently sent south to Dvinsk from the headquarters at Riga, has completed arrangements for the wholesale vaccination of the population in that region, some 400,000 persons. The vaccine is to be shipped from the Red Cross headquarters in Paris. Typhus, influenza, and dysentery are also prevalent in this region.

Trachoma in Algiers.—An epidemic of granular trachoma is sweeping the oasis towns of the Sahara desert. French resident doctors state that thousands of children are affected, but so far the adult population has been comparatively immune. Dr. Toulant of the Pasteur Institute of Ophthalmology, who has been conducting experiments on a herd of monkeys in an effort to isolate the bacillus, has informed the American Red Cross that eight of every ten children are affected.

Better Provision Urged for Tuberculous Discharged Soldiers.—As a part of its efforts to make better provision for the tuberculous among discharged soldiers, and at the same time to bring about an improvement in the campaign the United States Public Health Service is conducting against tuberculosis, Surgeon-General Hugh H. Cummins sent the following telegram to the American Medical Association during its recent sessions in New Orleans: "I desire to urge more active participation by the general practitioner and by general hospitals in the treatment of tuberculosis. To insure earlier diagnoses, properly train internes and other personnel, popularize treatment in the home climate, provide additional facilities. I earnestly indorse the resolution passed by the National Tuberculosis Association in 1916, recommending that general hospitals should admit tuberculous patients and provide separate wards for that purpose. Sanatoriums and specialists in tuberculosis will always be needed and we should have more of them, but I believe that success in the anti-tuberculosis campaign is largely dependent upon first, convenient facilities for observation and prompt treatment of patients with open tuberculosis and second, in a sharpened perception and higher degree of skill by which the family doctor will make early diagnoses or even forestall the development of clinical tuberculosis in the adult before a definite diagnosis is possible. To provide adequate care for tuberculous ex-service men and others, to protect infants from infection, enlist the aid of the general practitioner, allay phthisiophobia, and improve home treatment of tuberculosis, the opening of general hospitals to this most common of all serious diseases will materially assist."

Viennese Doctors Threaten Strike.—The doctors and surgeons of the Viennese hospitals declare that they cannot live on their present rate of pay, and threaten to go on a strike unless their salaries are immediately raised by the municipality. Their present remuneration is lower than that of the lowest day laborer and they claim that they should have pay at least equal to that of the washerwomen in the same hospitals. The lack of drugs

and the overcrowding in the hospitals of Vienna has made the task of the overworked medical staffs one that is almost beyond endurance.

Government to Buy New York Quarantine Station.—The House of Representatives has approved the taking over and purchase by the Federal Government of the quarantine station in New York Harbor. The purchase price is $1,395,275, which is the amount settled upon in condemnation proceedings. No opposition to the measure on the part of the Senate is anticipated.

Anthrax in Curled Hair Factory.—Five persons have died from anthrax in the past six weeks in Chicago. Three of these persons had been employees of the Chicago Curled Hair Factory, and, believing the disease was contracted by handling hair imported from Argentina, Health Commissioner Dr. John Dill Robertson has closed the factory. All firms that have purchased hair from the company recently are being warned to be extremely careful in its use. All the employees of this plant are being visited by the Health Department and blood tests are being made.

Disinfecting Polish-American Soldiers.—The American Army on the Rhine has undertaken the task of disinfecting 25,000 Polish-American soldiers who are being returned to the United States on American transports, after having served in the Polish army. This task is being carried out at Warsaw and Danzig. The work is under the care of a medical unit sent from Coblenz under the command of Col. Harry Gilchrist. The disinfection is being carried out owing to the fear that the returning soldiers might bring typhus fever to the United States.

Christian Scientist Father Convicted.—Andrew Walker of Bloomfield, N. J., has been convicted of manslaughter as the result of the death of his daughter Dorothy, whom he had had "treated" over the telephone and personally by Christian Science practitioners for diphtheria. There is only one degree of manslaughter in New Jersey, and the maximum penalty is five years. The jury in returning its verdict made a strong recommendation for mercy, and the judge has the power to make the punishment nominal. The counsel for the defense has stated that if necessary the case will be carried to the Supreme Court of the United States.

"The Modern Hospital," having outgrown its former quarters, has removed its offices to its own building at 22-24 East Ontario Street, Chicago.

Automobile Fatalities During April.—The report of the National Highways Protective Society for April shows that 82 persons were killed by automobiles in New York State. In New York City during April 50 persons were killed by automobiles, 19 of whom were children under 16 years of age.

West Side Dispensary Buys Site.—The West Side Dispensary and Hospital, located at 328 West Forty-second Street, has purchased the adjoining property at a cost of $50,000. A lying-in hospital costing from $50,000 to $100,000 is to be erected in the newly acquired plot.

Annual Report of Montefiore Home.—The annual meeting of the Board of Directors of this institution was held on May 2, at which time a report was submitted showing that the total income of the institution for the year was $494,249 and the expenditures $491,469. During the year the home has been able to open a semi-private ward of 50 beds and has instituted a system of occupational therapy. It was announced that a research department and laboratories would be re-established. In addition to an income of $10,000 from a fund established by Jacob Schiff, $15,000 a year has been pledged by some of the directors to meet the expenses of this work. Construction work on the new pavilion has been resumed and it is hoped to have this ready for occupancy by the end of the year. Plans for a new country sanatorium at Bedford Hills were also announced.

Sir William Osler, who died last December, bequeathed his medical and scientific library to McGill University.

Dr. Royal S. Copeland, Health Commissioner of New York City, sailed for London on May 9, where he will represent the city at the Housing Congress. Later he will attend the Public Health Congress in Brussels.

Gift to Polish Red Cross.—The American Red Cross announces a gift of 2,000,000 Polish marks to the Polish Red Cross to enable it to equip and maintain three hospitals in an effort to stay the further progress of typhus fever in that country.

Milk and Child Exposition.—A Milk and Child Exposition is to be held at the Grand Central Palace during the week of May 17, designed to educate the public as to the value of milk as a food and to emphasize that the New York Health Department has discovered the fact that many children of the poor are suffering from malnutrition due to lack of milk. It is hoped that the exposition will increase the consumption of milk in New York City and also that it may open a way whereby the poor can get milk at a reasonable price.

Dental Survey Shows Few Sound Teeth.—According to figures recently given out by the New York Association for Improving the Condition of the Poor, which has just completed an examination of the teeth of the children in three large public schools on the lower East Side of Manhattan, 1,382 children were examined, and 1,334, or 97 per cent., were found to have defective teeth. The total number of cavities found was 9,307, or 6.8 cavities per child. The most serious aspect of this survey is the vast amount of decay found in the first permanent molars.

Home for the Aged Celebrates Anniversary.—The Home for Aged and Infirm Hebrews recently celebrated its fiftieth anniversary. On this occasion Dr. S. Newton Leo, the institution's physician and surgeon, was presented with a silver loving cup.

Red Cross Scholarships.—Upon the suggestion of Henry P. Davison, ten scholarships in public health nursing will be offered by the League of Red Cross Societies to the Red Cross membership of stricken countries or to nations with inefficient Red Cross organizations. The course of study will be carried out at King's College, Women's Department, University of London, and will begin next October.

Child Hygiene Conference in New Jersey.—

The New Jersey State Department of Health has called the first conference on Child Hygiene of a State-wide character at Asbury Park, June 12-14. New Jersey is carrying on one of the most active child hygiene programs in the United States, having been granted the largest appropriation ever granted by any Legislature in the United States for this purpose, $150,000.

Society for Clinical Study.—This society will hold its regular monthly meeting in the reception hall of the New York Diagnostic Clinic, 125 West Seventy-second Street, New York, Wednesday evening, May 26.

Positions for Physicians.—The Manhattan State Hospital, Ward's Island, announces a vacancy for a medical interne at $1,200 a year and maintenance, and for an assistant physician at $1,300 to $1,800 and complete maintenance. This hospital offers exceptional opportunities for study and research in psychiatry and neurology, as well as instruction in hospital administration. Courses of instruction are given to physicians appointed to the resident staff. Opportunities for promotion are offered to physicians who are proficient in their work. Appointments are made by the Superintendent to the grade of medical interne upon non-competitive examination. The grade of assistant physician is open to physicians holding a license to practice in New York State who have had one year's general hospital experience. Further information may be had by addressing the Superintendent, Dr. H. B. Heyman, Manhattan State Hospital, Ward's Island, New York.

Obituary Notes.—Dr. ALFRED KIMBALL HILLS of New York, a graduate of the Hahnemann Hospital and Medical College, Philadelphia, died at his home on May 2, at the age of 80 years. Dr. Hills was a member of the New York Academy of Medicine, and formerly publisher of the *Medical Times*.

Dr. JOHN M. BENEDICT, a graduate of the Medical Department of New York University, in 1882, died of angina pectoris at his home in Woodbury, Conn., on April 23. Dr. Benedict practised medicine in Waterbury, Conn., for thirty years, retiring in 1913.

Dr. RICHARD J. P. GOODWIN, a graduate of Harvard Medical School, in 1885, and for many years a practitioner of medicine in Manchester, N. H., died in Malden, Mass., about April 21, at the age of 84 years. He had charge of the army hospital in Manchester during the last months of the Civil War and was for many years a pension examiner.

Dr. EDWIN L. CHASE of Shrewsbury, Mass., died suddenly at the home of a relative in Smyrna Mills, Me., on April 30, aged 50 years. He was a graduate of the Baltimore, Maryland, School of Medicine in 1898, and a member of the Board of Health of Shrewsbury.

Dr. CHARLES J. HELM, a graduate of Harvard Medical School, in 1887, died of pneumonia at his home in Peru, Ind., on April 27, aged 57 years.

Dr. F. W. NORTON, a retired physician, who formerly resided in Boston, died at the home of a relative in West Minot, Me., on April 25, aged 59 years.

Dr. WALTER W. GILMAN, a graduate of Harvard Medical School, in 1888, and a member of the staff of the Worcester City Hospital at the Memorial Hospital, died at his home in Worcester on May 2, aged 59 years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, April 24, 1920.

Conditions in Vienna.—At a meeting in Norwich the other day of "Save the Children Fund," the speaker was Mrs. Hawker, who had returned recently from a visit to Vienna, whither she had gone as a delegate from the "Save the Children" Conference, held in Geneva on Feb. 25, 1920. Mrs. Hawker, in the course of her address, gave some figures showing that owing to the lack of suitable food infants and young children in Vienna were in an appalling state. Still births increased in the year 1919 by about 20 per cent., the main reason being the under-nutrition of the mothers. The diminution of the population by still births and mortality of infants is evidenced by the fact that in normal years the surplus of living births compared to deaths amounted to about 8,000 yearly, while during the past four years there died in Vienna 80,000 more people than were born. Children naturally suffered the most and tuberculous disease especially played havoc among the young. In 1913, there were 6,430 deaths of children from tuberculosis; in 1914, 6,223; in 1915, 7,810; in 1916, 9,651; in 1917, 11,791; in 1918, 11,531. In addition to tuberculosis, rickets among young children is extremely rife in Vienna. According to statistics given by Mrs. Hawker to the writer, 90 per cent. of breast-fed babies are rachitic and a great many, perhaps the majority of those children who survive are cripples. There are said to be in Vienna at the present time 25,000 children partly crippled, partly suffering from tuberculous diseases of the bones and of the joints. Probably environment plays its part in the causation of this condition, as the sanitary and hygienic state of affairs throughout Vienna is of the most deplorable character. For example, in April, 1919, there were in Vienna 550,000 apartments, of which 41,000 consisted of only one room, and 254,000 of one room and a kitchen. Criminality among children has increased greatly. In Vienna in the year 1913, 1,848 children were guilty of penal offenses, while in the year 1917, 5,926 children offended in a similar manner. The speaker paid a generous tribute to the American Child Welfare Administration, which has been active in sending many poor children to Switzerland, Holland, Sweden and elsewhere.

State Aid for British Hospitals.—As with many British hospitals, in fact, as with practically all of them, the Norfolk and Norwich hospital at Norwich is appealing for funds to permit of its being continued on a voluntary basis. Its outgoings are considerably more than its takings, and it is in debt. At a meeting of the Governors of the Institution, held during last week, ways and means for helping it out of the slough into which it has fallen were considered. Dr. Samuel Barton, Chairman of the Board of Management, in the course of a speech discussing the situation, said that Norwich had a hospital second to none in the English provinces and they, the Governors, were naturally proud of having kept up with the times

in all the advances of medicine and surgery. They were quite up to date, but the expense of keeping in front was naturally great. As governors they could not recommend a drastic reduction of beds and expenditure, for by so doing they would reduce the efficiency and utility of the institution. The alternative to the voluntary hospital was a rate or State aided one, which meant whole-time officers, red tape, and forms strictly demanded, and the treatment of the sick a secondary consideration. Dr. Barton gave one or two impressions gained from his canvass of the public during the year. He divided the public into three classes—1. The class who do not give to any charity and are the enemies of voluntary hospitals and the chief supporters of the idea of rate aided hospitals. 2. A class which he called obsessionists. Their only wish was to die rich. They did not spend on themselves selfishly. Their only lament was that they would not be able to read in the *Times* of the thousands they had died worth. Although in his opinion not certifiable the obsessionist was a person of unsound mind, and to argue with him was worse than useless. 3. This was the most numerous class and the pleasantest to come into contact with. He referred to the charitable who were only too ready to give in a good cause. This class simply required educating as to the good work and needs of the hospital in order to make them respond freely. It ought to be the first duty of the governors to get on with the propaganda among this class. Another speaker at the same meeting also opposed to the hospital being put on the rates said that if it were run by the State it would cost at least £60,000 against the £40,000 it now costs because the honorary medical staff would have to be paid and the administrative staff would have to be larger. None of the speakers advocated the adoption of a pay system or a modified pay system. Indeed, the consensus of medical opinion in this country seems to be in favor of a continuation of the voluntary system and, perhaps, if the State does step in, only to supplement the voluntary hospitals and not to supplant them. However, there does not appear to be any valid reason why patients who can afford to do so should not pay according to their means, and that the hospitals should not be open to that large section of the British middle class, who now comprise the really poor.

Medical Degree for a Bone-Setter.—The petition of members of Parliament in favor of the medical degree *honoris causa* being granted to Mr. H. A. Barker, will be formally presented in a few days' time, when the full text of the memorial will be published.

Developments of Radiography.—Major G. W. C. Kaye, lecturing recently at the Royal Institution on "Recent Advances in *X*-Ray Work," described the development of the Coolidge tube. This he said had revolutionized *x*-ray research and would probably become the main instrument of the radiographical work of the world. A new method of taking fingerprints was also described. The hands are cleaned with alcohol and red lead is rubbed over them. Radiographing them reveals with great accuracy the details of the skin.

The Effect of Alcohol on the Duration of Life.—Dr. I. D. Lister in his presidential address to the Assurance Medical Society delivered March 3, 1920, remarked that alcohol was by no means exhausted as a subject for consideration. It was known that for certain select lives, with a very high standard of moral hazard in the risk, there was a low mortality among teetotallers; while Sir Dyce Duckworth in 1904 expressed an opinion in favor of the moderate use of alcohol by both the healthy and the sick. The experiments upon which the case for total abstinence rested were chiefly reaction and discrimination time experiments. They were, perhaps, conclusive as showing the temporary depression of nervous and psychic rapidity of action due to doses of alcohol. Lister submitted that such evidence was no criterion as to the effect on life duration. It might not be a good thing to be always energetic. That a drug capable of producing depression might produce annihilation of energy was one thing, but there were also drugs capable of producing exaltation of energy which might produce exhaustion. All that he felt himself able to say was that excesses were bad in either direction. Certain many abstainers were drug takers, even if it only were their tea that they took. To ascribe all the good effects on mortality, among certain excellent groups of lives, entirely to their abstinence from alcohol was unscientific, but inasmuch as total abstinence connoted other qualities making for longevity it was therefore to be favorably regarded in assessment. On post-war affections, such as soldier's heart, malaria, dysentery, wounds, amputations, the reasoned guidance of physicians and surgeons, not only of war experience, would be of the greatest help to us. Did rapid action of the heart over a prolonged period tend to cardiac or vascular degeneration earlier than if the heart pursued a placid course throughout? Were war neurasthenia and shell-shock things which increased mortality, now that we hoped there was no chance of their recurrence? Should they be "rated up" when the signs had disappeared? There was a great difference between the clinical diagnosis of the ill, and the insurance diagnosis of the apparently well.

Obituary.—The death occurred on April 13, 1920, of Sir Hugh Adcock, who for many years was chief physician to Mouzaffer-e-Din, prior to his succession to the throne of Persia. Sir Hugh, who was 71 years of age, was the son of a London surgeon, and after taking his medical degree, engaged in practice in Norfolk and London. In 1888 he went to Persia, and was presented by the Shah Nasr-e-Din with the first class Gold Star from the Imperial College, Teheran, for his services during the severe cholera epidemic of 1892. Sir Hugh was afterwards consulting physician-in-chief to the Shah.

Transmission of Syphilis as an Industrial Disease.—Despite the fact that the industrial transmission of syphilis has been understood for decades cases of such transmission continue to appear. Thibierge has recently reported two in cobblers from infected shoe pegs carried in the mouth and later thrown back in the common stock, and one in a carpet layer from a similar use of carpet tacks.—*Le Bulletin Médical.*

LETTER FROM GENEVA.

(From Our Regular Correspondent.)

GENEVA, April 15, 1920.

Psychic Disturbances in Influenza.—Psychic disturbances following influenza have not been uncommon in France or Switzerland, and they have been regarded as one of the most characteristic sequels of this epidemic malady, by some, particularly by Lemierre. These phenomena occur quite as frequently in patients who do not develop pulmonary infections and although alcoholism favors their advent, the appearance of intellectual disorders is not necessarily their etiological basis. The psychic sequelæ vary in intensity, some offering intellectual obnubilation and stupor, physical and mental prostration frequent in the severer form of influenza; in others there is a real transformation of the personality so that an individual ordinarily reserved becomes talkative and even playful. In patients who are usually of a happy disposition, the reverse is true. Cases of hallucination have been observed engendered by the toxi-infection and this form, when attenuated may be the prelude to grippal delirium. Many accidents and suicides can be attributed to the latter mental process or the subject may resort to acts of violence against other persons. At all events, no matter what the cerebral manifestations of the influenza may be, they are invariably followed by amnesia, at least that has been the experience here. It is usually during the febrile phase that the psychic disturbances are observed, usually retrogressing when the temperature has become normal, but they may persist for several days longer in severely infected cases. Their intensity is generally in direct proportion to the grippal infection, but nevertheless these psychic disturbances need not be taken into account when making a prognosis. So far as is known they do not give rise to suppurating meningitis and the cerebrospinal fluid has been found normal. The treatment of the psychic disturbances of influenza will be that of the disease itself, combined with hot baths or packs in the case of agitation and not with chloral or morphine.

The influenza at Pontarlier offered an interesting study. The epidemic, like all those occurring on the Swiss frontier, was very serious on account of its diffusion, malignancy and high contagious power. There were slight and even latent cases to be sure, and there were intestinal forms with diarrhea, frequently dysenteriform, and the nervous types with coma, impulsive delirium and in alcoholics, delirium tremens. But the pulmonary forms were especially prevalent, with single or multiple foci, occasionally generalized pulmonary edema, intense hyperthermia and a very irregular evolution. Death was commonly the result of cardiac failure or asphyxia. Tachycardia with collapse, great distress, oliguria, or even anuria announced the advent of cardiac failure. Intense dyspnea with marked increase of the respiration and thoracic pain, the dyspnea being out of all proportion with local signs, the suppression of the expectoration with persistency of the focal symptoms and cyanosis of the face and extremities usually gave warning of approaching respiratory failure within a day or two. Physiological misery, previous affections of the heart or lungs, deformities of the thorax, but above all alcoholism, particularly in subjects under forty years of age, were elements of great gravity. Death usually occurred about the end of the first week, but some instances of the fulminating type with death in thirty-six hours were observed, which were unduly common throughout Switzerland. An interesting fact was that quite frequently a facial erysipelas developed which renders quite plausible the part attributed to the streptococcus as the casual agent of respiratory complications. In patients with malaria of long standing the diagnosis was sometimes difficult, but when doubt exists quinine should be given, not only for its antimalarial properties, but as a cardiac tonic as well. The treatment resorted to by the local profession was cold packs when the temperature went above 104° F., bleeding and injections of camphorated oil, caffeine or sparteine, and as a general tonic cinchona was found very valuable.

Cancer in Animals.—Cancer of the tongue and lips in animals is an interesting topic to which Cadiot has recently called attention. He has pointed out the extreme infrequency of these neoplasms, but so far as the lips are concerned it is still more rare in horses than in dogs, while the commissure is the site of election of epithelioma with enlarged lymph-nodes. Care must be exercised in not mistaking true cancerous neoplasms for botryomycoma or actynomycoma; in cats the supposed cancroid is very often merely a microbic ulceration. As to cancer of the tongue, Cadiot has been able to collect seven authentic cases; three in the horse, once in an ox, once in a dog and twice in the cat, therefore four cases in herbivorous, as against three in carnivorous animals. Now, in all these animals the tongue is continually exposed to traumata, irritation and incessant soiling with gingivitis and alveolar pyorrhea. In spite of this, the tongue in these animals usually remains free from chronic lesions. The traumata leave only thin, elastic cicatrices which soon disappear and only exceptionally is there any thickening or induration of the mucosa. A persistent leucoplasia or epithelioma on the edges of the tongue are not observed, at least no instance has as yet been put on record and still the edges of the organ are the most exposed to traumatic irritation. These data are clearly of interest. The extreme infrequency of cancer of the tongue or lips in animals is evidently due to the inexistence of specifity in them which, on the contrary, in man is the principal factor for the development of cancers as well as their high morbidity.

The Pain of Membranous Pericolitis.—The dull pain in the right iliac fossa to which membranous pericolitis gives rise frequently leads to the erroneous diagnosis of chronic appendicitis. Its appearance at the very onset of the colic process is a moot question, but the bands of adhesions to which it ultimately gives rise and the resulting bends and kinks in the colon, are unquestioned. Grégoire of Paris has obtained good results by freeing the colon of the membranous

products surrounding and then fixing the colon to the peritoneum of the iliac fossa by a few sutures in order to prevent the return of the ptosis which is prone to be present and to hold the gut in its new position.

Treatment of Gangrene of the Lung.—Quite recently at Nancy an attempt has been made to treat pulmonary gangrene with the new arsenical preparations by intravenous injections. This treatment is to be resorted to without delay as soon as the diagnosis is made; it is not incompatible with the drugs ordinarily employed in this affection, so the Nancy physicians say, and although it has contraindications belonging to it, it is applicable to the majority of cases. Three cases have been observed in which pulmonary gangrene was cured without other treatment, two by intravenous injections of novarsenobenzol and one by intramuscular injections of hectine. The dose of novarsenobenzol was 15, 30 and 45 centigrammes in three successive daily injections, but after the third dose the intervals were increased as progressively larger doses were given.

2. The Milk Situation. Howard Swift.
3. The New Clinic. An Advance Movement in Child Welfare and Race Regeneration. J. Victor Haberman.
4. Intestinal Obstruction. E. A. Codman.

1. The Relation of Teeth to General Health.—Charles H. Lawrence reviews the literature on this subject, which he finds brings to light a vast deal of theory upon the relation of dental conditions to general health, but does not form a sound basis for treatment of patients. It may be regarded as proved in certain instances that dental sepsis does cause systemic disease. Therefore, a careful examination of the teeth should always be made, and the patient should be questioned regarding dental symptoms. If the *x*-ray findings alone are positive, extraction of useful teeth should be reluctantly performed, since results show that benefit is obtained in only a small number of cases and the extracted tooth is not always as bad as the *x*-ray indicated. It should not be forgotten that mastication is an important part of digestion, and that disorder of nutrition may rise from lack of teeth. Anemia and disorders of digestion may be due in some cases to dental sepsis—in others they are as surely caused by too radical extraction in its treatment. From the standpoint of cleanliness artificial teeth should not be permanently fixed in the mouth. From the medical point of view permanent bridge work and similar devices are not desirable. Such are the facts concerning the relation of the teeth to the general health. They should not be confused with theories. Until more clinical facts are available caution should be used in promising results from the extraction of diseased teeth.

4. Intestinal Obstruction.—E. A. Codman, in this issue, concludes the review of 41 cases of intestinal obstruction operated on during a period of twenty years, from which he draws certain inferences. The first of these is that modern surgical methods are adequate for the relief of obstruction if one takes into consideration the influence of early diagnosis. Of the 41 cases, 14 were fatal. Of the fatal cases four did not die of the obstruction, but of other causes, two or more weeks after the operation. Of the fatal cases all had had symptoms for more than forty-eight hours. Of the 27 which survived, 14 had symptoms less than forty-eight hours. The inference is that the forty-eighth hour in obstruction is more significant than in appendicitis. Bands and adhesions are the most common cause, although in about half the cases there had been no previous laparotomy. This was surprising, but was substantiated by the statistics of Fitz (1888); although in those days laparotomies were relatively uncommon. In a patient over 45, if there is no previous history of laparotomy and the onset is not sudden, cancer is much the most probable cause. Seventeen females and twenty-four females in this series the writer finds is in accord with previous statistics. A point particularly to be emphasized is the use of the Monks or Moynihan tube to remove the poisonous content above the obstruction. The use of the tube should never be given up because of the condition of the patient. A case which would die from the slight additional shock of this procedure without it would surely die from the septic absorption.

2. Encephalitis Lethargica.—John H. W. Rhein gives a summary of our present knowledge of this disease, and reports three cases. In all of these the lethargy was pronounced, though in two cases there was at times a mild delirious state, preceded in both instances by a lethargic state which lasted until death. Other points of interest in these cases were that they occurred during the epidemic of influenza and that with the lethargy there was associated a disturbance of the extraocular movements and what appeared to be a double ptosis; the responses which these patients gave to questions when aroused seemed to be perfectly lucid; the temperature changes were insignificant until shortly before death. The disease was usually ushered in by the appearance of catarrhal manifestations of the mucous membrane of the eyes, throat, and bronchial tubes. As a rule the symptoms developed gradually, though the onset might be sudden, as by the occurrence of a convulsion or fainting spell. Headache is common and diplopia a common symptom. Slight fever is almost always present. Somnolence, lethargy, stupor, and coma appear in about 80 per cent. of the cases. Paralysis affects the oculomotor nerve mainly and next in frequency the facial nerve. In some cases there are no localizing symptoms. A review of experimental work shows that further studies are necessary to determine the nature of the virus and its relation to influenza. The treatment is entirely symptomatic, though withdrawal of the spinal fluid may give relief if there is increased pressure.

5. The Relation of Focal Infection to Mental Disease.—Henry A. Cotton presents a study of focal infection in the patients of the New Jersey State Hospital carried out by the aid of modern laboratory methods. As a result of their efforts to detect and remove foci of infection there has been a decrease of 91 in the hospital population during the past nine months not accounted for by death or other ascertainable reasons. They feel justified in concluding that in the removal of foci of infection they are doing more for patients suffering from mental disease than they have ever been able to accomplish before. The teeth harbored the focus of infection in by far the largest percentage of cases, while the tonsils ranked second, and the gastrointestinal tract third as the site of the responsible focus.

3. Arsphenamine Reactions.—John F. Martin states that in large hospital clinics where syphilis is treated with various arsphenamine preparations, reactions occur more or less frequently, depending upon the care taken in preparing the solutions, the purity of the contents, the time elapsing between the making of the solution and its administration to the patient, the amount of arsphenamine given, operative technique and skill, and factors within the patient. Laxness in following the printed directions that accompany each ampoule of arsphenamine accounts for the greater number of reactions to treatment. One should note any departure from the normal lemon color of the brand of arsphenamine being used, and then immerse the ampoule in 95 per cent. alcohol for fifteen minutes to detect obscure cracks. Cracked ampoules are to be rejected. Using the directed technique for one brand of arsphenamine while preparing the solution of another will, in some cases, cause reactions. Giving too large a dose of arsphenamine at the beginning of a course accounts for some reactions. Lack of preliminary preparation for a treatment—a laxative the night before and a light breakfast four or five hours before—is sometimes the cause. When two or more reactions occur from a multiple ampoule solution, in the majority of instances the fault will be found in the technique of preparing the solution, and the usual cause will probably be hypoalkalinity. Factors attributable to the patient, after both arsphenamine and the technique of preparing the solution have been excluded, include allergic idiosyncrasy, an inherited dominant susceptibility to arsphenamine medication; anaphylaxis, protoplasmic sensitization from repeated doses; blood synthesis reactions, in which arsphenamine becomes altered or precipitated from causes not understood, or ascribed to excess of carbon dioxide in the blood, or faultily prepared arsphenamine solutions; and the nitritoid reaction, ascribed to the action of arsphenamine in destroying spirochetes and liberating large quantities of bacterial protein to which the tissues have become sensitized. The Herxheimer reaction is attributable to the stimulating activity of non-sterilizing doses of arsphenamine. Reaction symptoms occur singly or in syndromes. The most common type of table reaction is the vasomotor syndrome assigned to the vasodilating action of arsphenamine. Insufficient alkalinization of arsphenamine solutions accounts for a large number of this type of reaction. When repeated reactions of this type occur, preceded by a number of arsphenamine injections without reaction, epinephrin deficiency as a possible factor in causing the reaction is to be considered. Preinjection of epinephrin tends to prevent this type of reaction. Another type of reaction is the "spine pain," characterized by stabbing pain in the lumbosacral region. Kolmer and Yagle state that arsphenamine causes hemolysis and that this action is increased by hyperalkalinization. Dilute solutions of neoarsphenamine (0.9 mg. in 90 c.c. or more of water) are claimed to cause hemolysis, while concentrated solutions (0.9 gm. in 30 c.c. or less of water) are not hemolytic. In addition to these reactions there are others due to functional and organic impairment, causing certain viscera to be more susceptible to arsphenamine. Dermal reactions appear to be due to too large doses of arsphenamine. Among the grave reactions are dermatitis exfoliativa, toxic jaundice, hemorrhagic encephalitis, and gangrene.

7. Use of Mercurochrome-220 as a Germicide in Ophthalmia Neonatorum.—C. A. Clapp and M. G. Martin report having used dibromoxymercuryfluorescein (mercurochrome-220) in four cases of gonococcal ophthalmia neonatorum with exceedingly satisfactory results. They find that a 2 per cent. solution can be used with impunity and with only a slight burning effect for the first few seconds. Though it leaves a red stain it is no more objectionable than argyrol, and will not produce a permanent stain, as occasionally happens with silver preparations. In the cases reported there was a marked improvement after its use was begun, and apparently a more rapid convalescence.

8. The Metabolism of a Dwarf.—Fritz B. Talbot calls attention to the recent work of Benedict and Talbot, about to appear in the forthcoming publication of the Carnegie Institution of Washington, which gives for the first time the complete curve of the basal metabolism of children from birth to puberty, and makes possible comparisons which in the past were not feasible. The basal metabolism of a dwarf was studied, which compared with the normal showed that his total metabolism for twenty-four hours was 780 calories against an average of 900 calories for normal boys of the same age. Although his metabolism was slightly diminished, it was almost within the normal. When the total calories of this dwarf were compared with the total calories of normal boys of the same weight it was found that he was producing more calories than the average, the total calories being 780 against 675 for normal boys. This was slightly above the possible deviation from the normal. His metabolism studied from the point of view of body weight was found to deviate markedly from the normal. The study shows that the intensity of his metabolism is greater for each unit of body weight than that of a normal boy. The result of the metabolism studies on this boy showed that in order to make him gain in weight he must receive as many calories as a normal boy of the same age and a great many more calories per kilogram than a normal boy of the same age or weight. This finding corresponds to what was found to be true in atrophic infants who required from 160 to 180 calories per kilogram before they gained.

7. The Plating of Simple Fractures. F. D. Saner.
8. Experimental Medicine and Venereal Diseases. William F. Snow and Thomas A. Storey.

2. Incidence of Nose, Throat, and Ear Diseases Among Aviation Candidates.—David Ranken submits statistics based on the examination of over 56,000 candidates for the aviation service, young men between the ages of 18 and 23, from all parts of the country, showing that aural disease appears seriously to affect 2.8 per cent. of this part of the population. These statistics, the writer states, could form the basis for the estimation of the incidence of other diseases in this group. The obvious conclusion is drawn that much remains to be done before the amount of nose, throat, and ear disease affecting the youth of Great Britain could be said to have been brought down to a negligible factor.

3. Delayed Arsenical Poisoning.—George S. Strathy, C. H. V. Smith, and Beverley Hannah, report 58 cases of arsenical poisoning following the administration of "606" preparations. Most of these cases were seen in military hospitals, though several additional cases have come under observation in civil practice. Of these 58 cases 47 showed symptoms referable to the liver—namely, jaundice, decreased digestive power, and liver atrophy. Eight were fatal, and at autopsy showed marked atrophy of the liver. Atrophy of the liver was noted in cases which ultimately recovered. This condition could be diagnosed by the *x*-ray. Dermatitis occurred in eight cases, five of which were severe, with marked exfoliation. Peripheral neuritis was observed in two cases. Albuminuria was present in over 50 per cent. of the cases. Edema was found in two cases. The onset of the symptoms seldom occurred until five weeks after the administration of salvarsan

had ceased. The earliest symptoms of salvarsan poisoning of the liver were bile in the urine, albuminuria, loss of appetite, and jaundice. These symptoms should be looked for in all patients receiving salvarsan medication, and on their appearance the administration of salvarsan should cease. Where evidence of liver damage is present the diet should be reduced to a minimum. Dermatitis with atrophy of the liver was observed in one patient who received arsenic in the form of Fowler's solution. Where the onset was sudden, with stupor and vomiting, death supervened in a few days.

5. Unusual Cases of Intestinal Obstruction.—J. A. Cairns Forsythe cited four unusual cases of intestinal obstruction to illustrate the difficulties with which the surgeon may have to contend in the diagnosis and operative treatment of intestinal obstruction. These cases were: (1) Acute angulation at the hepatic flexure from pericolitis, with rupture of the taeniae cecum; (2) adenomatous polypus of the ileum, accompanied by a chronic intussusception; (3) acute intestinal obstruction from traction diverticulum of the ileum, and (4) strangulation of a loop of the ileum by an adherent appendix epiploica of the sigmoid. The writer points out that traction diverticula are of rare occurrence, but they have been found in all parts of the alimentary tract. They are small funnel-shaped pouches produced by retraction of chronic localized peritonitis, by cicatrices in the wall of the intestine, or by inflammatory processes in adjacent organs. Adhesion of the bowel wall to a tuberculous lymphatic gland is one of the commonest causes. Mesenteric gland disease may lead to intestinal obstruction in various ways. The first case was probably unique in that two of the three taenae coli of the cecum were ruptured.

1. Lecture on Soldier's Heart and War Neuroses: A Study in Symptomatology.—Sir James Mackenzie, in the introductory part of this lecture, calls attention to the need for a presentation of disease which conforms to the aspect of disease presented by the living subject. Thus far there has been no orderly classification of the large mass of symptoms which have been recognized. He therefore attempts a classification based upon the mechanism of their production, as follows: (1) Structural symptoms—that is, those based on a modification of the tissues of the organ, and which are chiefly revealed by physical signs. (2) Functional symptoms—that is, symptoms due to modified or deranged function of an organ. (3) Reflex symptoms—symptoms due to reaction on the central nervous system or on the nervous mechanism of organs. It is to the last group that he especially directs attention. In considering this he discusses the mechanism of an ordinary stimulation, of the radiation of sensation, of a motor reflex, and the mechanism of radiation in disease, and emphasizes the fact that if we apply a mechanical stimulus to the skin we produce sensation peculiar to the nature of stimulus, as, for example, touch, pain, heat, or cold; if we apply the same stimulus to the viscera or to the serous surfaces of internal structures of organs we get no response or rarely a response of a different nature. He had repeatedly tested in the conscious human subject the various organs by cutting, stitching, or tearing, and no sensation was elicited. The insensitiveness of the viscera in its full significance has not yet been grasped. In the testing of the sensibility of organs very imperfect methods have been used. No conclusions should be drawn as to the sensitiveness of an organ which has been stimulated through a structure which is itself sensitive. Nearly all conclusions have been drawn from observations made by pressing on the organs through the sensitive abdominal wall. Many observers state that they have demonstrated the sensitiveness of an organ by observing its position by various methods, such as the *x*-rays, and later by pressing over it and eliciting pain. The error here lies in the failure of the observer to take the precaution of excluding the sensitive external body wall. When in testing the sensibility of organs pain is elicited, a clear conception of the stimulus giving rise to it should always be obtained. There is evidence that a mechanical stimulus only produces pain when a vital process is set in motion.

4. Operative Treatment of Ulcerative Colitis.—O. Lockhart-Mummery believes the best treatment of chronic ulcerative colitis is by frequent washing through with saline solution after an appendocostomy opening has been established. The operation should be performed as soon as the diagnosis has been made, and not left as a last resort, although it may sometimes succeed even then. The diagnosis should always be confirmed by sigmoidscopy.

March 25, 1920.

Encephalitis Lethargica.—Maier sums up our knowledge of this affection as follows: Up to 1916 we had no definite knowledge of this malady. Its nearest congener is infantile paralysis, which, however, has a pronounced spinal component and affects children by preference. As for any relationship with grippe the more the two are compared the less the suggestion of any kinship. Encephalitis lethargica appeared two years before the pandemic. In grippe encephalitis there are no cortical disturbances. Many old practitioners have informed the writer that in the pandemic of 1889-90 there was nothing comparable to sleeping sickness. It is true that patients affected with encephalitis, when placed in wards with influenza cases, did not contract the latter, but this negative evidence is not decisive of anything. The same thing may be said of subjects with other diseases, notably the "false grip" cases. The coexistence of the two maladies in certain localities speaks rather for a common predisposition to both affections, based on lowered resistance. Again, influenza itself lowers the general resistance to disease, so that encephalitis follows in its wake. The new disease is proving very instructive in the demonstration of cerebral physiology, but it is a serious matter, despite its small incidence, with its 30 per cent. mortality; and while it comes and goes in the space of three months it can reappear in subsequent waves. Despite the low diffusibility—it is rare for more than one case to occur in a family—it should for the present be considered as mildly contagious, and a certain degree of isolation and quarantine observed. The symptomatology is multifold, and at the onset many conditions may be mimicked as hysteria, dementia precox (catatonic form), and fugues, myoclonus, and chorea. Fever is present in 100 per cent., busy delirium in 78 per cent.; lethargy in 82 per cent., muscular rigidity in 78 per cent. Diplopia and strabismus are somewhat less common, but this may be in part explained by defects of observation.

Pro-German Naïvetés.—Cruchet refers to a recently published work by a German author on experimental bacteriology and infectious diseases in which entire mass innovations of American origin are ignored. Such works are usually regarded as a boycott of French, American and other scientists. But this attitude may be unjust, for a similar work by an Austrian contains the short but significant passage that unfortunately he was unable to obtain access to the recent labors of any but German and Austrian scientists. The work in question had for its subject lethargic encephalitis. There should be some discrimination shown in these cases. The general present attitude of the Teuton, if not repentant, is at least conciliatory, and there is no evidence yet of any new Teutonic propaganda. On the other hand, there is every reason to watch for and anticipate such activities.—*Journal de médecine de Bordeaux.*

(*Continued from page* 814.)

SECTION ON PEDIATRICS.

First Day—Wednesday, April 28.

DR. FRITZ B. TALBOT OF BOSTON IN THE CHAIR.

Chairman's Address.—Dr. FRITZ B. TALBOT made this address, in which he brought out the fact that many people both inside and outside the medical profession were giving more and more thought to the subject of child hygiene. He expressed the belief that in the future his subject would attract more attention and would draw to the solution of its problems greater minds than it had done in the past. It was pointed out that research into the cause and nature of disease had assumed an importance which was not recognized a decade or more ago, and as a result of the work done in the past ten years the general practitioner was able to treat successfully to-day many diseases that he was formerly unsuccessful in treating. We had also gained a knowledge of normal physiological processes of the child's body with which we could compare pathological processes, and that had been very important because up to date we had not had any normal standards with which to compare the pathological. The speaker also emphasized the great impetus which preventive pediatrics had received during the war owing to the campaign and propaganda of Children's Year. At the International Conference called at Cannes by the Red Cross it was stated that next to the then present typhus fever epidemic child welfare had assumed the place of greatest importance of all the specialties represented there. The establishment of normal health in childhood laid the foundation for normal healthy adult life. This foundation might be laid either by attending the individual child or by classes in clinics. Dr. Talbot discussed somewhat in detail the deficiency of pediatric teaching in our medical schools, and particularly the failure to teach infant feeding. The medical student in order to get his degree had to care for twelve obstetrical cases; why should he not care for twenty normal infants, both on the breast and on the bottle, before he received his degree. In this way he would obtain actual first-hand knowledge which he never got from books, and when he went into private practice he would be familiar with what, perforce, he would have to do. Many diseases were becoming extinct—could not the time used in learning their recognition and treatment be used to better advantage in learning prevention? Every so often it was important that the relative value of subjects should be balanced anew so that teaching could be readjusted to the times. At the present time there was the necessity of understanding social questions that had an influence on health, home life, etc. The social element of medicine could well be taught along with the scientific aspect at the bedside at the same time that clinical medicine was taught. That would bring the pediatrician back to the place that the general practitioner formerly held with so much pride. The teacher of pediatrics should cooperate with those specializing in other subjects, and particularly with the obstetrician with the object of enabling the student to acquire a knowledge of the theory and practice of antenatal care. It would be ideal if the student could observe the prenatal care, be present at the delivery and then follow the child for five months after birth in a certain number of cases before receiving his degree.

The Treatment of Indigestion in Children.—Dr. JOHN LOVETT MORSE of Boston presented this paper, in which he stated that digestion might be disturbed by decreased powers of digestion or increased work in digestion. Decreased powers of digestion might be due to diseases other than digestive, physical or mental overfatigue. The treatment consisted in relieving diseases other than digestive, and removing causes of overfatigue. The regulation of intervals between feedings and methods of taking food was often enough to effect a cure. In the more severe cases there was intolerance for individual food elements, often with intestinal fermentation from abnormal bacterial activity. Examination of the stools would reveal which food was badly borne and caused fermentation. A microscopic inspection was often sufficient to determine this, but should never be depended upon alone. The microscopic examination should therefore always be made. This was not a difficult matter, and required but a few minutes. In fat indigestion the stools were large and semi-solid, with the odor of butyric acid, and contained a considerable amount of mucus. Microscopicolly, fat was present, more often as fatty acids and soap. The stools of sugar indigestion were usually loose, greenish, containing acetic or lactic acid and often mucus. In starch indigestion the stools were usually loose, brownish in color, contained acetic or lactic acid, sometimes butyric acid, and occasionally mucus. Almost invariably the starch was changed partially into dextrin. In general the bacteriological examination was not of great importance in diagnosis, for usually no additional information was obtained. Usually the character of the intestinal flora could be ascertained from the reaction of the stools. There was no place for the so-called digestants in the indigestion of infancy, for there was probably never an insufficiency of hydrochloric acid or pepsin. The treatment consisted in the regulation of habits and the regulation of the quantity of food to the capacity of the individual child. If it was necessary to cut down one food element, this should be made up by substituting another food element in a quantity sufficient to make up the required number of calories. Then the food element that caused the trouble must be given in a small quantity, and increased as fast as would be allowed. The diet list must be written out explicitly and the number of calories indicated. A list of foods and their caloric values should also be given to the parents. Dr. Morse said he had found that almost all parents were sufficiently intelligent to use these tables. In cases in which there was marked clinical evidence of fermentation it was difficult to say what proportion of the disturbance was due to bacteria and what proportion to chemical processes. It was probable, however, that the original difficulty was not due to bacteria. The bacteria could not be changed by giving bacteria by the mouth, but only by changing the intestinal contents; and this must be done by diet. The only exception to this was the gas bacillus, the growth of which might be inhibited by butyric or lactic acid. There was no place for the use of drugs in the treatment of the indigestion of childhood except for the temporary relief of symptoms. Cure could only be brought about by the regulation of life and diet. Recovery was a matter of years sometimes, but was usually certain, provided treatment was kept up for a sufficiently long time.

Dr. L. W. HILL of Boston said he wished to bring out three points, as he had been seeing a great many of this group of cases. First, Dr. Morse got results which were equalled by very few men in this country, not only because he had seen a great many cases, but primarily because he took infinite pains. That was the one thing of importance; one must be willing to work, to follow the cases closely, and to see them often. One must take as much trouble with these cases as with a difficult surgical or obstetrical case. Sometimes it took, not weeks or months to effect a cure, but years. Second, with reference to the relation of bacteria to the food supply, Escherich had brought out in 1886 that the intestinal bacteria depended upon the food supply, and by changing the food supply one could change the bacteria. Two types of bacteria were distinguished, the putrefactive and the fermentative. If the intestine was infected with the fermentative bacteria one should withdraw the carbohydrates and substitute protein food. If the putrefactive bacteria were present one should withdraw protein food and substitute carbohydrates. That was one of the most important things in infant feeding. Dr. Hill said that if he had to choose one particular principle in infant feeding that was the one he would adhere to. The intestines were swarming with bacteria, and if the infant was overfed

the bacteria seized the food and decomposed it, so if the baby was overfed an indigestion with fermentation resulted. There was no use telling the mother to give this or that; one must figure out absolutely what the child should have and give the mother an ironclad diet list, containing exactly what the child should have for each meal. Never give directions by word of mouth, but always written directions. Trust nothing to the judgment of the mother, but have it all on paper.

Dr. CLIFFORD GRULEE of Chicago called into question the statement Dr. Morse had made to the effect that you could not change the intestinal flora by administering another type of bacilli by mouth. He said he did not see how they were going to account for certain phenomena unless one admitted that bacteria introduced by mouth did show growth in the intestines. Typhoid bacilli were introduced into the mouth and developed and multiplied in the intestines. It was also true that some types of dysentery were produced by bacilli introduced by way of the mouth. His experience was contrary to that of Dr. Morse. It seemed to him there was no scientific reason why lactic acid bacilli introduced by the mouth could not be taken up by the intestines. The latest results obtained by the use of the duodenal tube showed that there was a definite relation between the bacteria in the stomach and those in the duodenum in various types of nutritional disturbances.

Dr. L. T. LE WALD of New York said he wished to indorse what Dr. Morse had said, but he wished to supplement it by a few remarks on what to do when treatment failed. In other words, his work in the study of children had been along the lines of roentgenological diagnosis in cases that did not yield to ordinary methods of treatment. He had a little more distinct view of the subject than the man who saw it only from the standpoint of the pediatrician. Their observations in obscure conditions in adults ten years ago were about what they were in pediatrics today. A more careful study with the *x*-ray of cases of indigestion that did not yield to ordinary methods of treatment frequently showed anatomical anomalies or definite mechanical obstructive lesions that could be dealt with effectually only by knowing the exact nature of the lesion. Dr. Le Wald described a number of these anomalies and mechanical obstructions.

Dr. ISAAC ABT of Chicago agreed with almost everything Dr. Morse had said, and said he was particularly impressed by the fact that Dr. Morse had laid stress on the fact that gastrointestinal disturbances might be produced by constitutional disturbances. He doubted whether there was such a thing as indigestion pure and simple. Indigestion was but one step in general metabolic disturbance. The problem was not so difficult as some had thought. It was a question of finding what the difficulty was, and of diminishing the amount of food element that was causing the trouble or altering the food entirely. So far as placing great reliance on the examination of the stools, he doubted whether this was the most important element in the diagnosis. Sometimes one found fat when the food was perfectly correct. Personally he had found little help from the examination of the excreta.

Dr. MORSE, in closing the discussion, said he did not think Dr. Grulee's argument was very good when he spoke of typhoid bacilli in the intestine. Typhoid fever was a systemic infection, and infectious dysentery was a disease of the intestinal walls. By giving bacteria by the mouth they could not be implanted permanently in the intestines, unless the food was also changed so that they had a favorable medium in which to grow. Dr. Jacobi had brought out a most important point when he once said that in the modification of milk one should mix brains; it was most important in making stool examinations that one should mix brains in the interpretation of results. There was a great deal to be learned from the examination of the stools, but if one thought because he saw a few fat globules or a little starch that the child had fat or starch indigestion he had better not examine stools microscopically. One must first take what he saw in the normal child as a basis for forming a judgment as to what was abnormal, and he would have to use brains in the interpretation of his findings. The reaction of the stools furnished more information than any other single thing.

The Treatment of Indigestion in Children from Six to Twelve Years of Age.—Dr. HARRY M. MCCLANAHAN of Omaha read this paper, which was based upon the study of 96 school children between the ages of six and twelve years. This was the age at which children were subjected to the stress of school life, the age at which the permanent teeth erupted, and the age at which they began to get a little away from close parental supervision. In 24 of these cases there was a history of nervousness, and three of these children had to be sent away from home before anything could be done for them. In 27 cases three were distinctly diseased tonsils, and 10 of these were associated with adenoids sufficiently large to cause mouth breathing. These were operated on and all received benefit. Ten of the tonsillectomy cases, however, were operated on without benefit to their general condition. Twenty-five children in this series had distinctly bad teeth, and one point that had impressed him was that these children would not chew their food properly because of pain. Three children who had malocclusion were sent to the orthodontist and showed distinct improvement after treatment. Indigestion in the largest number of these children appeared to be due to high protein feeding and neglect of fruits, cereals, and leafy vegetables. Those showing obstinate constipation were fluoroscoped for the purpose of ascertaining if there were anatomical defects present. All had the urine examined several times. Dr. McClanahan recalled that some years ago he had read a paper on the significance of indican in the urine. All of these children complaining of indigestion had an excess of indican in the urine. There were five alimentary glycosurias which disappeared under proper diet. Practically all of these children had some nervous symptoms, such as increased irritability, restlessness, grinding of the teeth, etc. Fourteen had eneuresis, and 10 of these recovered under rational treatment. Of the series, 52 were constipated and five only suffered from emesis. Seven of the children had intestinal parasites. In 25 cases the abdomen was distinctly enlarged. In those children having epigastric tenderness and pain on pressure these symptoms were associated with a distinctly red tongue. From these findings the essayist drew no conclusions. In the treatment of indigestion in children of this age the most important factor was the cooperation of the mother. It was his rule in all cases to write a simple diet, giving what the child could have rather than what he could not have. A psychological factor of importance was the gaining of the good will of the child. If there was one factor in the treatment that was of importance it was that rest and regularity in sleep were of the greatest value in the physiological restoration of the nervous system. Eleven of the nervous children were kept out of school. The importance of regular bathing was also stressed. The essayist said he wished to confess that he used drugs in the treatment of these cases. He found that before these children came under his observation most of them had been drugged to the extreme and he felt that it was better for the children to have some drug under the direction of the average physician than to take drugs of the mother's choosing. The main object of the drug was to get the bowels regular. He had given paraffin at bed-time and had found nux vomica valuable given after meals. This was a good reminder of the necessity of keeping regular habits. If one obtained the cooperation of the mother and child these were most satisfactory cases to treat and the doctor received due credit.

Dr. LAURENCE DEBUYS of New Orleans said they should all feel greatly indebted to Dr. McClanahan for bringing up this subject inasmuch as this was a period in the child's life which frequently did not receive sufficient attention. The foundation of the future individual was laid, it was true, during the first two years of life and influences were more important the nearer they approached his birth time. However, one could not build a good foundation in infancy and then let the structure go uncared for later on. At the period Dr. McClanahan had chosen for discussion one could not watch the child as closely as in infancy. Indigestion at this period of the child's life had to be considered from two view points, that

of the child and that of the child in relation to his surroundings. It had been well said that some children were born nervous, some acquired nervousness and some had nervousness thrust upon them. It was sometimes necessary to take these nervous children away from their homes in order to get results. The teeth should receive attention and regularity of habits should be insisted upon. It was important to ascertain the amount of food that the child could take care of and then see that he received this food at regular intervals and nothing between meals. The food should be plain and wholesome rather than palatable. Unfortunately, too often the parents allowed a child to have what he liked rather than what was best for him. Dr. DeBuys condemned the practice of drugging children and said that too often the child at this period of life had already become dependent upon drugs, especially as regarded bowel movements. He also condemned the use of glycerin suppositories and soap in infancy; if it was necessary to use something water should be used. The stimulating effect of glycerin and soap made the child insensible to the normal desire to stool.

Dr. Henry Dwight Chapin of New York observed that there were many factors that entered into indigestion in childhood, but that he wished to mention one only and that was to emphasize the deleterious effect of the lack of proper rest. An interesting experiment had been performed in the case of a few children in the public schools of New York. They took the undernourished children in the public school across the street from the Post Graduate Hospital and gave them a midday meal and then weighed the children to observe the effect. They all gained in weight except about half a dozen. They found that the reason these children did not gain was because they did not get enough rest. By having these children sleep an hour every day they were made to gain in weight. Some children played too hard and overexerted themselves and this was an important factor in their malnutrition and indigestion. A little more rest would cure some of these cases.

Dr. John Lovett Morse of Boston said he wished to corroborate what Dr. McClanahan had said. He did not think they stood so differently on the question of drugs as Dr. McClanahan had intimated. In his paper he had said that he had no use for drugs except for the treatment of symptoms but they were not used with the idea of curing the condition. He was glad to hear that Dr. McClanahan used nux vomica because that was the one drug he used in cases of this kind. He had found it wise to get the cooperation of the child rather than of the parents. There was one form of treatment that might be called psychotherapeutics which he had taken advantage of. Before examining the child he saw the mother first and had her tell him what the child had eaten for the past two meals. He then examined the child's abdomen and told the child what he had been eating; after that the child was afraid to disobey orders as regarded diet for fear when he examined him again he would find it out.

Dr. Fritz B. Talbot of Boston emphasized the importance of rest in the treatment of these cases. He said it was interesting to hear the different views as to why rest was beneficial but that did not make so much difference so long as the child got the rest.

Dr. De Vilbiss of the U.S.P.H.S.. said it was important to make the child understand that this was his own problem. In their work they had had to make the best of conditions as they found them and to work with such material as was at hand. They told the mother about the child and what should be done; perhaps she would act and perhaps not. They put the child on the scales and showed him that he was underweight and that was a mark against him. The child then immediately became interested and wanted to know why he was underweight and what he should do to come up to the standard. He was willing to do almost anything in order to "go over the top" with the other children. They first corrected physical defects—teeth, tonsils, adenoid, etc.—and then by gaining the cooperation of the child they were able to get results.

Dr. George Dow Scott emphasized three points with reference to the successful treatment of these children: (1) the neglect to feed stewed and raw fruits which acted as a laxative, diuretic and tonic to the stomach and intestines; (2) the advantages of semisolid foods, cereal with enough milk to put on the cereal, with toast and cooked food. Meals should be regular and nothing should be permitted between meals; (3) another thing that was important was bathing. Bathing was a better tonic than any drug. A bath fifteen minutes before meals was a tonic to the nervous system and helped digestion.

Dr. Frederick Moore of Des Moines called attention to another source of error in handling these children. It was important to get a history of the previous diet of the child because frequently it was deficient not only in quality but in quantity. The temptation was for the physician to give a complete and special diet at first. When that was done the mother lost interest in a short time. One should not make a great variation from the customary diet at first but should make changes gradually. A careful history of the child's diet was as important as the diagnosis.

Dr. McClanahan, in closing the discussion, said these made very satisfactory cases for treatment because one got results. By caring for these cases of indigestion in childhood much invalidism in later life was prevented, for undoubtedly the foundation of later life was laid in childhood.

The Relation of Acquired Food Dislikes of Childhood to the Ills of Middle Life.—Dr. C. Hilton Rice, Jr., of Montgomery, Ala., contributed this paper. He first discussed the phenomena of life and nutrition from the view point of biologic chemistry, showing that a defect in nutrition might not be immediately perceptible, but was nevertheless often cumulative in its effect. Against this background the following facts of general observation were set up: (1) All healthy adults and children with few exceptions, ate a variety of foods. (2) Many children, particularly in the second and third years, left to eat what they liked, turned to the carbohydrates and formed dislikes for essential foods, especially milk, eggs, fresh meats, and green vegetables. (3) Many middle-aged sufferers from disturbances of metabolism had food dislikes that dated back to childhood. These individuals had often been anemic and constipated from childhood. After a careful exclusion of other etiological factors the conclusion seemed warranted that the total or partial absence of essential foods over a long period of time might account for much disease of middle life. This disease was only the masked and remote effect of the gradual, cumulative action of malnutrition on tissues and organs over long periods of time. Some of the conditions that might be related to defective nutrition dating from childhood were hypertension, gastric and duodenal ulcer, visceroptosis, etc.

Dr. W. W. Butterworth of New Orleans expressed the opinion that Dr. Rice had presented a new viewpoint in reference to disturbances of nutrition. Instead of looking backward as the internist did he was looking forward, and while it might be difficult to prove his assertions there was much in them to commend itself to one's attention. Take, for instance, rickets which was brought about by deficiency in certain food elements in infancy yet the dire results were seen later in bone deformities stunted growth, etc. Pellagra might also be cited as a condition that showed the far-reaching effects of a deficiency in certain food elements. Many of these conditions due to food deficiencies were slow in onset and might have disturbances in digestion over years and years before finally definite disease resulted.

Dr. Talbot said he thought Dr. Rice had in mind the same idea that he had when he composed his address. We were all searching back to the cause with the idea of prevention in the background. It was going to be difficult to prove many things but it was obvious that many of the diseases of adult life had their origin in childhood. In regard to digestion disturbances and food likes and dislikes, Dr. Talbot said he had very little experience with patients who were on an extremely unbalanced diet. Education in his community was such that most people came to know what a good diet was. There was, however, a certain group of children who had food dislikes and did not get a well balanced diet. Most of these food dislikes came in certain types of families in which the history

showed asthma, hay fever, or urticaria. and they had food idiosyncrasies due to anaphylaxis. One must bear in mind that food dislikes might be due to anaphylaxis.

Dr. MAY G. WILSON of New York stated that in 1916 they had made a study of diet in a large group of children and found that outside of potatoes, tomatoes and lettuce there was a lack of green vegetables in the diet. In many children who were in the lower grades in school, milk was omitted for the diet and tea substituted. By the time the children were ten or eleven years of age they began to use condiments and acquired a dislike for the essential foods. In a group of 2000 children only five per cent. used green vegetables.

Dr. O. M. GILBERT of Boulder, Colo., said it fell to him to treat a great deal of tuberculosis and he had observed that a great many of these patients did not like milk or eggs and never could take meat. He felt that this defective diet or lack of dietetic training was an important factor in relation to tuberculosis. There were a few cases with anaphylaxis but they were very rare. With the average individual it was only a matter of taking time and of gradually adjusting the patient to the proper diet. Irving Fisher should be credited to having called attention to the injurious effects of an excess of protein diet after middle life. but a proper protein diet was essential during the formative period of life, and lack of a proper protein diet was a factor in developing not only conditions like pellagra but of tuberculosis as well.

Dr. RICE, in closing the discussion, said the conclusion he had reached on this subject had come to his mind too recently for him to give statistics, but that he had observed that in Alabama one of the commonest diets of children was bread and cane syrup with too much candy and too many ice cream cones between meals, and that most of these children did not like green vegetables. From the point of view of the pediatrist they were in a position to look forward and see the effects of the food dislikes of childhood on the metabolic disturbances of middle life better than the internist who got only a fragmentary history.

Three Pertinent Questions on Maternal Feeding.—Dr. WILLIAM A. MULHERIN of Augusta, Ga., read this paper in which he considered the following questions: (1) Should our textbooks unqualifiedly state that intercurrent pregnancy was an indication for immediate weaning? (2) Might we not question the advisability of immediate weaning in mild typhoid fever? (3) Should not more positiveness exist in our textbooks regarding the advantages of complemental feeding over the method of alternating the breast and the bottle? In discussing the first question the essayist emphasized the advantage of slow weaning when the baby reached a certain age and the breast milk was no longer sufficient to properly nourish it. The evidence seemed to show that uncomplicated pregnancy did no more than weaken the milk and perhaps diminish the quantity so that there was no need for immediate and abrupt weaning. It seemed advisable that in uncomplicated pregnancy weaning should be brought about slowly. With reference to the question of immediate weaning in typhoid fever, the writer stated that in severe typhoid fever there could be no question that immediate weaning was advisable. In mild typhoid fever, however, with the diagnosis made from the tenth to the twelfth day of illness, the breast secreting freely, a positive Widal with the baby's blood, the mother feeling equal to and desirous of nursing her baby he felt that it might be permissible to continue the baby at the breast and to piece out, if necessary, with complemental feeding. He cited three cases in which this course was followed with no ill effect and with possible advantage to both mother and child. It was evident that if the child had been nursing for ten or twelve days, during which time the mother had typhoid fever without it being known, the danger of the child contracting the disease was greater than after the condition had been diagnosed and care taken to avoid infection. Again the wear and tear on the mother of sudden weaning was perhaps greater than any ill effects of continuing to nurse the infant. There was not much danger of the mother transmitting typhoid fever to the baby through the milk and the child could be protected from infection from other sources. In reference to the third question, he felt that greater stress should be laid on the advantages of complemental feeding over the method of alternating the breast and the bottle. It was well known that stimulation was an important factor in increasing and preserving the milk supply and when the bottle was alternated with the breast the latter received less stimluation and the milk supply decreased. This was an important matter and should be stressed much more than it had been.

Dr. JOHN LOVETT MORSE of Boston said that as regarded the weaning in cases of uncomplicated pregnancy, it seemed to him that it was impossible for a woman to properly nourish three people, the infant at the breast, the child *in utero* and herself. It had never occurred to him that when weaning was advised in pregnancy that abrupt meaning was meant—he thought it meant weaning the child slowly. With regard to complemental feedings, Dr. Morse emphasized the fact that he thoroughly believed in breast feeding and that he believed a great many more mothers could nurse their children than did do so, and that such women should be made to nurse their children. Of course there was a limit to the amount of milk the civilized woman of today could produce. Personally he had had no luck in re-establishing breast feeding when it had once been abandoned. There was no question but that it was better to give a complemental feeding than to alternate the breast and bottle, but one had to take into consideration the state of society in which the mother lived. If she was at home it was best to nurse the baby at every feeding time. but if she was a woman with other cares and duties it might be well to substitute the bottle at one or two feedings a day. There was a certain class of mother who produced more milk if this plan were followed than if she attempted to nurse her baby every time. The one thing, however, which increased the milk supply was to use the breast.

Dr. JAMES D. LOVE of Jacksonville, Fla., stated that in his experience he had seen uniformly bad results from the sudden withdrawal of the baby from the breast where the mother had mild typhoid fever. The danger to the baby was practically nil much less than from sudden weaning, and the mother was saved the discomfort and nervous wear and tear of having the milk withdrawn artificially; she also had the satisfaction to be derived from being able to nurse her baby. He believed that after the baby reached the age of two or three months it should have one bottle of milk daily. Provided the milk supply was not very scant the mother's health was often improved by this rest and the quality of the breast milk was materially improved thereby. He believed Dr. Morse expressed the sentiments of the section in reference to the advisability of withdrawing the baby from the breast in uncomplicated pregnancy and febrile disturbance.

Dr. I. L. VANZANDT of Fort Worth, Texas, cited several instances in which mothers with typhoid fever and women who were pregnant had been successful in nursing an infant at the breast.

Dr. ALFRED J. SCOTT, JR., of Los Angeles also cited an instance in which a mother with walking typhoid fever had nursed her baby. He had always advised the discontinuance of nursing during pregnancy though the weaning was effected gradually, but the babies in California were not subject to gastrointestinal disturbances to the same extent as in the East.

Dr. WILLIAM WESTON of Columbia, S. C., pointed out that in animals and primitive man the fact of pregnancy was not a reason for the cessation of nursing the offspring. If that were true why should one insist upon immediate weaning in more civilized people? He thought the answer must depend upon how the mother was getting on and how the baby was doing. Personally he believed that if both were getting along well one should leave things as they were.

Dr. BLOOM of New Orleans said that in his judgment the right thing to do was to wean the child rapidly at the time the diagnosis of pregnancy was made.

Dr. MULHERIN, in closing the discussion, said that he would find no fault with the textbooks if everyone interpreted them as Dr. Morse had done, but the state-

ment was made that one of the indications for immediate nursing was the occurrence of pregnancy. Personally he did not advocate nursing after pregnancy had taken place, but slow weaning. With regard to the complementary and supplementary feeding. the point to be made was that the way to increase the milk supply was not to relieve the breast of work but to make it do more work, as in that way the capacity for work was increased. In pregnancy there was seldom a toxemia that called for immediate weaning, and in the South there was great danger in sudden weaning.

How Pediatric Teaching of Nutrition May Affect the Nation's Welfare.—Dr. HENRY DWIGHT CHAPIN of New York read this paper in which he dwelt upon the important part that nutrition played in the development of the child and hence in the future of the nation. The pediatrician was the one most frequently consulted with reference to diet and nutrition in childhood, and hence was in a position to perform an important function in national affairs. That we had not given sufficient attention to the subject of child welfare in all its aspects had been shown by the results of the draft examination which revealed the fact that one in every four of our young men of draft age was physically defective. An investigation as to the extent of malnutrition among children in certain New York public schools was made and 20 per cent. of the school children were found undernourished. This condition was not limited to the poor but was found among all classes of society. The question that suggested itself was to what extent these physical defects and this malnutrition were the result of the teaching of faulty theories of nutrition. The literature of infant feeding has been based upon the theories of pediatric authorities. It was time to test these theories and see if they were borne out by experience and facts. Animal experiments had shown that poor growth and a satisfactory gain in weight might go on together. Real growth was not simply the storing of water and fat in the tissues. After emphasizing the importance of breast feeding Dr. Chapin pointed out certain errors in their teachings. We had been taught that the suitability of a food depended upon the quantity of protein, carbohydrate, fat, etc., that it contained. But it must be remembered that there were many forms of proteins, fats, carbohydrates, and mineral substances. Some proteins would produce growth and some would not, so it was easy to see how one might go wrong by basing his estimate of food values simply upon chemical composition. It was quite customary to add bicarbonate of soda to cows' milk to neutralize the acidity, but frequently cognizance was not taken of the fact that heat rapidly changed the bicarbonate of soda to carbonate. This procedure, though useful at times, must be done carefully. Again the fat soluble and water soluble vitamines of MacCollum played an important part in nutrition. Here it had been shown that the water soluble B was rapidly destroyed when bicarbonate of soda was added to the food, so that this procedure must be eradicated if milk was to have its full nutritive value. The popular teaching had been that food values were useful in proportion to the amount of heat they produced on combustion, this being expressed in calories, but it had been shown that much nutrition did not depend upon combustion. There were those who advocated cereals and milk as the best form of food for infants and children. The cereal was used not only for its nutritional value but to adapt the cows' milk to the infant's digestive tract. Milk mixed with cereal formed an efficient food provided a sufficient amount of antiscorbutis was added. The practical advantage of such a dietary was demonstrated on a large scale in Denmark during the war, where the people were given a ration of bread made of bran, wheat, and other cereals, potatoes, cabbage, and some milk. This proved a very satisfactory diet, and practically all our experience in matters of nutrition showed the efficiency of a diet of cereals and fresh vegetables. The real value of protein depended upon its containing the correct kind of amino acids and not upon whether it was an animal or a vegetable protein. Dr. Chapin quoted figures to show that as a transformer of food the animal was very expensive. A thousand bushels of grain would support five times as many people as though the same amount of grain were transformed into meat. The pediatrician could render no greater service to his country than to start children in life with foods that were suitable physiologically, simply and inexpensive. If he acquired the taste for such foods he would carry it into adult life. One of the future sources of protein food would be the soy bean, which contained much protein, fat, and heat. All possible sources of food should be searched to find other food supplies than those we now had that would be both nutritious and economical. Experience and results must be the final test in any plan of nutrition.

Dr. JOHN A. FOOTE of Washington, D. C., congratulated Dr. Chapin on his paper and on having emphasized the need of active interest on the part of this Section in public education, not only of the physicians, but of the lay public, in the matter of food values. The United States Public Health Service went a little further than Dr. Chapin had done in interpreting the statistics of he draft. Dr. Chapin said that one man in four was found to have some defect; the United States Public Health Service said one out of three men had some physical defect. When we remembered the large number of men who were examined and that this meant that there were at least a million men of draft age suffering from a physical defect which prevented them from doing the work that they might otherwise do, we could appreciate what this meant economically. Possibly the relation of these defects to the diseases of childhood was not apparent at first. Sir Arthur Newsholme, a short time ago in an address, stated that the same condition was found in England and he believed that we had not understood the importance of having the functions of child welfare week vested in local and national health departments. Dr. Foote also called attention to the need of better infant mortality and birth registration statistics.

Dr. L. W. HILL of Boston said it was the impression among physicians as well as among the laity that children needed a great deal of protein food in order to thrive and grow. He did not think the standard of two grams per kilo was correct. There were no accurate figures as to the requirements; what little we knew had been handed down from book to book and from mouth to mouth. He cited an instance of three husky boys in one family ranging in age from six to twelve years, all perfectly healthy and athletic, who had always eaten vegetables and never any animal food. These boys weighed from ten to fifteen per cent. above the average of boys of their age and were taller and larger in every way. He had had the chemist at the hospital work out the nitrogen metabolism of these boys and he found that they were receiving an adequate supply of that element.

Dr. CHAPIN, in closing the discussion, emphasized the point that there was a wide field of usefulness here for the pediatrician, not only in treating the individual case but in connection with social and economic questions. With the improvement of the condition of laboring men they had come to think they must have porterhouse steak and other foods that were luxuries. The pediatrician had the opportunity to do a great deal in cultivating a taste in early life for simple and nutritious food which would be carried up to adult life and would have a great influence in solving social and economic questions that were now causing so much disturbance in our national life.

The Clinical Value of Vegetable Oils in Certain Abnormal Conditions of Infancy and Childhood.—Dr. GEORGE DOW SCOTT of New York read this paper in which three classes of cases were studied: (1) Inanition. (2) A subnormal period following gastroenteric conditions, such as malnutrition, marasmus, etc. (3) Conditions such as secondary bronchopneumonias, in lysis or crisis following acute gastrointestinal intoxications. The fats were poor in oxygen, rich in carbon and hydrogen. After describing the physiology of fat digestion, Dr. Scott pointed out that the primary function of the fats was to furnish heat and that the higher the proportion of carbon and the lower the amount of oxygen the greater would be the heat-producing power of foods. The amount of fat needed by an infant could not be stated in terms of calories but depended upon the fat tolerance of that individual patient. The fat tolerance varied greatly in both physiological and pathological conditions. In health fat absorption varied

between 90 and 98 per cent. The excessive ingestion of fats retarded the emptying time of the stomach and delayed normal secretion so that vomiting or regurgitation of the food might occur. Healthy children assimilated solidified fats, but the sick or delicate child might reject them. Such patients thrived best on a fluid fat or oil, one the melting point of which was at about the body temperature. Such a fat was easily emulsified and digested. It was practically immaterial whether cod-liver oil, cotton-seed oil, peanut oil, sunflower, soy bean or other oil was employed so long as the little patient enjoyed it. His observations, however, inclined him to prefer olive oil, which was easily digested and absorbed and could be pushed except during the torrid heat of summer. Rosenberg had pointed out that olive oil was a strong cholagogue. The percentage of fat in olive oil was much more constant than that of cream. Olive oil consisted of stearin, olein, and palmatin. A number of cases were cited to show that given with malt extract it served to bridge over the time when the amount of carbohydrae or protein had to be limited in various conditions of malnutrition or following acute illness.

Second Day—Thursday, April 29.

Acrodynia.—Dr. WILLIAM WESTON of Columbia, S. C., contributed this paper, in which he said that the general impression seemed to have been that this was a Southern disease, or one confined to particular sections of the country. On the contrary this disease was found universally and was probably more frequent in the West than in any other section of the country. The Surgeon General's library reported a great paucity of literature on the subject. There were records of previous outbreaks in this country. Acrodynia had been confused with malaria, pellagra, and beriberi. The purpose of the paper was to ask physicians to be on the lookout for this disease in order that it might be studied and further information regarding it might be obtained. Though the etiology of acrodynia was unknown, the fact that it generally occurred as an epidemic suggested that it was probably due to some organism. The children attacked by this disease lost appetite, became listless, some manifested gastrointestinal symptoms, in some there was diminished weight, and diminished reflexes had been noted. There was often profuse perspiration and the hands and feet became cold, swollen, and tender, and in about one-half the cases were painful to the touch. Photophobia, conjunctivitis, and gingivitis had been observed. Of his eight cases all had gotten well but two. A point that had impressed him was that he did not feel that anything he had done for them had been of any benefit except in one case in which a balanced diet of vegetables, eggs, and milk had seemed to be beneficial. There were descriptions of an epidemic of this or a similar disease in Paris, in 1828. Several German writers had also described the condition under various names. It had been observed in barracks among soldiers where the conditions were the same yet in one barracks one set of symptoms would predominate and in another barracks these symptoms would be absent and another set of symptoms would be present. The first symptom was pain in the hands and feet with tingling and burning. These sensations and the pain were greatly aggravated at night and in wet weather. Many skin manifestations had been described, and edema sometimes occurred confined to the extremities. The skin dermatitis was different from that of pellagra and it did not seem to be due to any specific dietetic error. The prognosis under favorable circumstances was fairly good. There was no specific treatment known for the disease at the present time, though diet and hygiene were important factors in the treatment.

Dr. A. H. BYFIELD of Iowa City reported that during the past few years he had had 14 cases of this disease and that it was so definite, so clear-cut, and so unmistakable that the nurse had in several instances made the diagnosis before the doctor saw the child. Even when the characteristic eruption on the hands was absent the internes had been able to make the diagnosis upon the extraordinary picture of wretchedness which the child presented. One characteristic thing was that the child preferred to bury his head in the pillow and suffered from parathesia of the extremities. There were very few diseases that aroused one's sympathy to the extent that acrodynia did. The skin dermatitis was sharply differentiated from that of typical pellagra. Cases were reported in which the teeth came out. The speaker had observed no very striking change in the gums. He had observed a double keratitis and a pulling out and falling out of the hair. There seemed to be an extensive involvement of the fifth nerve. Anorexia was sometimes very striking, and in some cases this became so severe that it became necessary to resort to stomach feeding. The nature of the diease was that of a sensory polyneuritis. In the first case he saw he made a diagnosis of trophoneurosis. In his cases the question of diet had been gone into as carefully as possible, and a number of the cases were in breast-fed babies. In only one or two cases did the diet present anything that was open to reproach. All the cases had a leucocytosis, some as high as 27,000. Reflexes were sometimes present, sometimes absent. The spinal fluid findings were negative. Pellagra usually had a history of gastrointestinal disturbance at the onset. In practically none of the cases of acrodynia was this stressed, but rather a respiratory factor was prominent. Jacobi gave a brief description of acrodynia as a complication of diphtheria, and the speaker had been impressed by finding a diphtheroid organism in the nose; the diphtheroid organisms might be distinctly toxic though he knew that they were in disrepute as etiological agents at the present time. He had been impressed by the fact that though a scientific diet containing antiscorbutic vitamine was given the parathesia continued for weeks and months. He was inclined to think that respiratory infection if it was not primarily responsible at least played an important rôle; if the diet played a rôle it must have been a slight one. They were inclined to think they were dealing with a polyneuritis because at autopsy it was found that the anterior horns in the mesial aspect had lost their power to take stain and were degenerated.

Dr. JOSEPH GOLDBERGER, U.S.P.H.S., Washington, D. C., stated that he had been interested in acrodynia because of its possible relation to pellagra, though he had not seen anything that he was prepared to say was acrodynia. Some of the symptoms he thought were very like those of pellagra. The loss of weight, the edema, and the eruption were part of the picture of pellagra. The older descriptions of acrodynia emphasized certain definite things in respect to the eruption. In the older descriptions the eruption was spoken of as favoring the palmar surfaces of the hands and feet; it was known that the palmar surfaces of the hands and feet might be affected in pellagra. Dr. Goldberger said his suspicion would be that they were dealing with a nutritional condition in some way allied or related to pellagra. As he believed was the case in pellagra there was not a distinct specific condition but a combination of symptoms due to corresponding defects in diet. There was a range in dietetic defects and therefore a range in the manifestations of those defects. At a certain point the defect in the diet caused a certain clinical manifestation which might be considered as coming under acrodynia. Further along one would have pellagra and then edema. If one went still further up the scale he would find the manifestations of the gastrointestinal tract and still further along the nervous mnaifestations. One could not regard this as settled but he regarded it as a very useful hypothesis and a suggestive line of research. In studying these cases it would be extremely valuable if the clinician would record not only the clinical manifestations but would make careful note of the diet of the individual for a considerable period of time prior to the first manifestation of the disease, possibly a quantitative statement of the ingredients of the diet for a considerable period of time.

Observations on the Salt Content of Breast Milk.—Dr. WARREN R. SISSON and Dr. W. DENNIS of Boston presented this paper, which was read by Dr. Dennis. He stated that the fact was recognized that the standard amounts for fat, carbohydrate, and protein used in the diets of infants had been established in large measure. It was also recognized that a large class of infants fed on so-called rational mixtures might develop intestinal disorders. Attention had been attracted to the relative and absolute proportions of fat, carbohy-

drate, and protein with absolute disregard to the mineral content of the diet. It was assumed that the salts being in excess in breast milk had no effect on nutrition. During the last five years relatively simple methods had been devised for the determination of the mineral constituents of the blood and it had been a simple matter to adapt these for the estimation of the salts in milk with a quantity of milk as small as 10 c.c. About one year ago they started a study of the mineral constituents of breast milk and of the ordinarily used modifications of cows' milk with the idea that by a study of this kind it might be possible to trace the connection between obscure intestinal disorders and the mineral content of the milk. About 400 samples of breast milk were taken from the first day to the eleventh month. They found that during this time the chloride content was not changed and that the average was about 50 mgs. to 100 c.c., or 0.5 gram to the liter. This was about the average figure given in the textbooks. They felt, however, that these averages were of little value because of the very great variation in the chloride content in different mothers. Samples of milk were taken at different hours fo the day from 6 A. M. on, and these showed the chlorides excreted in a perfectly uniform way and with little change from day to day. In some mothers, however, particularly those who were nervous, tremendous variations occurred from hour to hour. They might start with 20 milligrams, go up to 50, and then fall back again. In looking up the histories of the infants in these cases it was found that though nursing their mothers they were not gaining as they should be. It was too early to draw any conclusions but they had found that same result uniformly. They had also examined a large number of formulas for bottle-fed infants in Boston and found that the ordinary salt content was about 75 per cent. But this was not the case with the whey mixtures used in the younger infants. In these whey mixtures values up to 200 were frequently found and these children frequently continued to have gastrointestinal disturbances. It seemed probable that there was some relation between the salt content of milk and nutrition.

Dr. Fritz B. Talbot of Boston said he was more or less familiar with this work and thought it opened up interesting possibilities. When they were feeding babies on whole milk mixtures and for various reasons put them on whey, cream and sugar, it was sometimes noticed that the babies had diarrhea, and they often noticed in private practice that babies on breast milk had more movements than they thought these babies should have. This work suggested that the chlorides were the background of the diarrhea, but it did not tell why one baby could take chlorides and another could not. Another point was the clinical observation of Dr. Sisson that the character of the nervous system of the mother who had high chlorides in her milk was apt to be less stable than that of the mother whose milk went along the level supposed to be normal. Much more work must be done to settle what this meant. It was a new field and opened interesting possibilities.

Chronic Nephritis in Children.—Dr. Lewis Webb Hill of Boston made this presentation. He stated that acute nephritis in children was usually a long drawn out affair and that the nephritis could not be called chronic until the albuminuria had existed for a year. The chronic nephritis of children differed from that of adults because in adults we were dealing with a kidney that had gradually become damaged while in children the kidneys had been suddenly damaged. In adults there were usually concomitant cardiac conditions which were as a rule absent in children. The paper dealt only with the mild type of chronic nephritis. Tonsillitis seemed to be the most important etiological factor. They had never seen a case due to dental trouble though they thought it might occur. In these mild cases there was usually a small amount of albumin, casts, and red blood cells. The blood pressure was usually normal or below normal. This form of nephritis was differentiated from orthostatic albuminuria, in which the albuminuria was temporary and due to posture and the urine did not contain red blood cells and casts. The two hour functional test of Mosenthal was studied and found to be a most practical test in children. It was found that the normal phthalein for children was higher than for adults. An excretion below 50 per cent. meant severe damage to the kidneys. Blood urea examinations were made and led to the belief that damage to the kidney in the mild cases was not sufficient to cause marked urea retention. In the treatment of these cases general hygiene was most important. The lives of these children should be carefully supervised. Plenty of rest, physical and mental, and plenty of good nourishing food were essential. The nephritic child might bathe in water 70 degrees or over but the surface of the body should not become chilled. The tonsils and teeth should receive attention. The tonsils which were the cause in many cases should be removed if there was the slightest suspicion that they might be the source of infection. It was of the utmost importance to guard against acute infections, since the kidneys were hypersensitive and should not be called upon to eliminate a toxine of any kind. It was a mistake to restrict diet too closely. The diet of these children might include meat and eggs in moderation, a moderate salt intake, and plenty of water. There were three prognostic possibilities: First, the kidney might recover entirely after several years; second, a severe and fatal chronic nephritis might follow; third, a contracted kidney might result, giving rise to the picture of chronic interstitial nephritis. He had not seen the third occur. It was quite possible to recover from the mild type of chronic nephritis. A normal phthalein output was not of much value as regarded prognosis, but an abnormal two hour test meant a damaged kidney, though not necessarily a severely damaged one.

Dr. C. M. Wahrer of Fort Madison, Iowa, said that these cases of nephritis in children were usually secondary infections following tonsillitis, rheumatism, etc. They were more frequent in boys than in girls because boys subjected themselves to greater exposure. They had been told that diet had a great deal to do with it but he would suggest warm clothing. One should be cautious in the use of drugs in these cases because an irritating drug might cause an acute axacerbation of the nephritis in chronic cases. In regard to the prognosis, his experience was that it was favorable rather than unfavorable. The majority of these mild cases usually made a recovery, but these cases should remain under the care of a physician and be watched closely for a long time.

Dr. John Lovett Morse of Boston expressed the opinion that one of the most difficult things in connection with these cases was to determine where the subacute nephritis ended and the chronic began. Almost all the cases that started as acute ran into subacute and chronic, so that one did not know what length of time made the diagnosis. Speaking of the preventive treatment of these cases, the vast majority of physicians were satisfied if they succeeded in getting the urine free from albumin once, but one could not call a patient well on one negative examination. The patient was not well until the urine was microscopically clear after centrifuging. His plea was to endeavor to prevent the development of chronic nephritis by such means as Dr. Hill had spoken of.

Dr. George Dow Scott of New York said that he had intended to say just what Dr. Morse had said, namely, that they knew very little about where subacute nephritis ended and chronic nephritis began. At the Willard Parker Hospital in New York they saw a great many of these cases following the acute infectious diseases and it had been observed that the younger the patient the more quickly recovery took place, so that the prognosis depended to a considerable extent upon the youth and the early nutrition of the patient. Dr. Scott did not agree with Dr. Hill in reference to the giving of animal proteins; they took away animal proteins and gave vegetable and fruit proteins instead. Bathing and fresh air were important. In the more acute cases the water should be warmer than need be for normal children, and the air at least 70 degrees.

Dr. H. M. McClanahan spoke of the results of early nephritis in adult life and cited cases showing that some cases apparently made perfect recoveries, while in others serious conditions developed and proved fatal. He had never seen acidosis in these cases. He believed it was more likely to occur in adults with contracted kidneys. He did not believe that chronic nephritis was

always a mild thing in childhood; they saw children with severe chronic nephritis just as they saw it in adults. So long as there was sediment and red blood cells in the urine one should be very careful in allowing the child to be up and about. They called cases chronic when they had lasted about a year but that was purely arbitrary.

Infantile Spinal Progressive Muscular Atrophy (Werdnig-Hoffmann.)—Dr. EDGAR J. HUENEKENS of Minneapolis presented this paper. After reviewing the literature of the Werdnig-Hoffmann and Oppenheimer syndromes, he discussed the evidence for and against their identity. He presented for comparison the differential diagnosis of Marburg showing that Oppenheimer had termed the condition indicated by his syndrome as amyatonia congenita and had described it as (1) congenital; (2) usually single; (3) generalized hypertonic; (4) atrophy masked and not grossly apparent; (5) tendon reflexes absent; (6) stimulated by electricity; (7) course usually marked by improvement. The Werdnig-Hoffmann description was as follows: (1) Acquired in early infancy; (2) usually familial; (3) localized atrophies, usually beginning in the pelvic region and spreading; (4) atrophy easily recognized and apparent; (5) tendon reflexes proportional to atrophies; (6) reaction of degeneration; (7) course of the disease progressive, the child becoming a mere skeleton at four or five years of age. The essayist analyzed these syndromes and expressed the opinion that they were extreme types of the same disease. He described the anatomico-pathological basis as being the same in both conditions. He then reported a case of typical Werdnig-Hoffmann type of necropsy findings which supported the conclusion that amyatonio congenita and Werdnig-Hoffmann disease were extreme types of one and the same disease. He called attention to the fact that this was the first necropsy on a typical case of Werdnig-Hoffmann disease in this country.

Dr. FRANK C. NEFF of Kansas City regretted that Dr. Huenekens did not read his autopsy findings, but felt that there was such a variation in the symptomatology that he could scarcely accept them as the same condition. He thought the diagnosis had to be based on the autopsy findings. He cited a case which he had been puzzled in classifying. It had appeared early in life but was not familial and had shown features of both conditions.

Dr. JOHN ZAHORSKY of St. Louis thought that between myotonia and Werdnig-Hoffmann disease there was a wide distinction and it would take a great deal of study on the part of the pathologist to convince him that they were the same disease. The course of the diseases was entirely different. The Oppenheimer disease was a congenital disease in which the baby did not commence to use its muscles early but gradually developed; he had such a case now which was gradually approaching normal. Another case had died not of the disease but of an intercurrent infection, while the Werdnig-Hoffmann cases went from bad to worse and died of paralytic symptoms and complications.

Dr. HUENEKENS, in closing the discussion, said he was glad Dr. Neff reported his case for he though it furnished additional evidence that they were one and the same disease. His case was a typical amyatonia congenita in the beginning. The point to be emphasized was there was no difference in the pathology between these diseases. The improvement that seemed to be noted in Oppenheimer's disease was only temporary; these patients all died later just as they did with Werdnig-Hoffmann disease.

Newer Ideas of Heart Disease Applied to Pediatrics.—Dr. RICHARD S. EUSTIS of Boston presented this paper in which he reviewed the work of Lewis, Barringer, and Rapporte with reference to the differentiation of functional and organic heart disease as it had been applied in the army and made a plea for its adoption by the pediatrician in dealing with cardiac conditions in children. He pointed out that the systolic murmur should be considered merely as a signal for a more careful examination of the heart. Systolic murmurs were of imporotance in children only where they were due to congenital heart disease. Many children with poor exercise tolerance fell into the effort syndrome group. The significance of a low pitched diastolic rumble, reduplicated second sound, presystolic crescendo were discussed. In certain respects the findings in children were somewhat different from those found in adults. The determination of enlargement of the heart was easier in children than in adults. In adults the transverse diameter of the heart was one-third to one-half the internal diameter of the chest; in children this measurement was not so certain. For this reason slight or doubtful enlargement of the heart was of little value in diagnosis. Definite enlargement meant cardiac disease. It was safe to regard as potential cardiac those children who had had rheumatism or chorea. The determination of the functional capacity of the heart was of great value. It should be remembered, however, that exercises carried out under observation often introduced a nervous element which gave a wrong impression. Dr. Hill presented an analysis of a series of 52 children to whom the principles employed in cardiac examination in the army were applied. In this series were 28 normal children, while the remainder exhibited various kinds of murmurs and there were a few suspicious cases. In the series were 19 children with systolic murmurs in whom there was no etiological factor and 15 of these were considered to be normal hearts. The series was considered too small to warrant conclusions, as definite information could only be obtained by following these children into adult life. He felt convinced, however, that if the principles applied in the army were applied to children a great many children now much restricted in their manner of life could be returned to normal life.

Dr. GEORGE DOW SCOTT said he considered it a very difficult thing to differentiate between functional and organic heart disease. It had frequently been his experience to find at autopsy that a condition which he had thought was functional turned out to have been organic, and then many times the reverse was true.

Dr. JULIUS HESS of Chicago said he believed it would be a good plan to adopt Dr. Eustis' method by which he used the exercise tests employed in the army in the study of cardiac conditions in children. Many children in whom organic cardiac disease was diagnosed on the basis of a loud systolic murmur were restricted in their lives so that they did not develop properly and their education was interfered with. It was certainly desirable to differentiate these children from those having organic heart disease. He said he felt as Dr. Scott that in the majority of cases he was not able to distinguish between functional and organic heart disease. A knowledge of the things Dr. Hill had brought out should make them much more careful in giving a prognosis on one office examination.

Dr. A. J. SCOTT, JR., of Los Angeles mentioned that in his experience in teaching he had found that the students did not know what a normal heart was. This applied not only to medical students but to men in active practice.

Dr. J. M. DODSON of Chicago suggested that better term than normal was "range of the normal." There was no such thing as a normal heart. The student was apt to take as his criterion of a normal heart the first heart he examined. There were no two hearts exactly alike, but slight shades of difference within a normal range.

Dr. ISAAC ABT recalled that twenty to twenty-five years ago the German authorities made the statement that there was no such thing as a functional murmur in a child under two years of age. That led to confusion in writing and thinking of doctors all over the world. Organic murmurs might be both congenital and acquired, and might occur at any age. With reference to diagnosing disease of the heart, it was well to remember that the heart might be diseased in any layer —the pericardium, the endocardium, or the myocardium. The myocardium was frequently affected after acute infections and there was scarcely an acute infection that did not leave its mark on the heart muscle. When in doubt as to whether there was a lesion after having made a complete and careful examination he thought one might say there was no lesion; if, however, one found certain definite changes, such as an accentuated second pulmonic, especially if there was an insufficiency of the mitral valve and some cardiac enlargement, one could be certain the lesion was organic.

Dr. EUSTIS, in closing the discussion, said he was glad to hear Dr. Scott say he had difficulty in distin-

guishing between functional and organic cardiac conditions. That was the reason he was so enthusiastic over this method of determining the condition of the heart by functional tests. Such tests must be interpreted with caution, however.

Circulatory Reactions in Normal Children After Exercise.—Dr. MAY G. WILSON of New York presented this contribution, which she said was from the Nursery and Child's Hospital and Cornell University Medical College. She stated that exercise was necessary for the development of the normal child and hence it was important in the child with chronic valvular disease to decide how much exercise might be allowed in a given case. The determination of this matter on the basis of clinical symptoms or subjective statements was open to error, hence an accurate method of determining exercise tolerance was desirable. It was well known that the heart reached the limit of its powers before the skeletal muscles. According to Mackenzie, the functional efficiency of the heart depended upon it reserve powers. The test applied was based upon the circulatory reaction to muscular exertion. Heretofore the reports of the circulatory reaction to exercise in children had been limited to changes in the pulse rate. Estimation of the blood pressure in children had not been considered to be of value. The present study undertook to ascertain whether the circulatory reactions were similar to those found in adults and whether anything could be found to act as a guide or check to determine the exercise tolerance. Observations were made on 20 normal children between the ages of six and twelve years. Repeated observations were made following the termination of the graduated exercise on pulse rate, systolic blood pressure, and clinical symptoms. Over 500 tests were made, representing 150 complete experiments, which consisted in three or four graded test exercises with one or two iron dumbells varying from three to ten pounds in weight, swung from the floor to a position over the head from ten to sixty times. The blood pressure readings were made immediately upon the termination of the exercise and at two minute intervals. The effect on pulse rate of increasing amounts of exercise was noted and the time required to reach normal. The normal curve of systolic blood pressure immediately after the termination of moderate exercise was plotted, and variations in the systolic curve after increasing amounts of exercise noted. The conclusions reached were that circulatory reactions to graduated exercises obtained in normal children were similar to those reported in adults. It was found that there was a constancy of circulatory reactions immediately following similar graduated exercises at two day intervals over periods of weeks in a given individual. It was shown conclusively that exercise tolerance could not be determined by the pulse rate. The systolic blood pressure curve, however, was significant and of great value in determining exercise tolerance. In overfatigue this curve showed an increased period of rising, a delayed rise or delayed summit, and a prolonged period of falling. In general the increase in breathlessness, dyspnea, and fatigue were directly proportional to the delayed rise and prolonged fall of the systolic curve. These experiments had also demonstrated that by means of graduated exercise the exercise tolerance of a child could be increased.

Dr. ALEXANDER LAMBERT of New York pointed out that the value of Dr. Wilson's work was that it showed that the human organism worked as a whole from the beginning of life to the end and that what was true of the adult cardiac muscle was true of that of the child. The test described did not depend upon reaching any particular number, but upon a definite blood pressure curve, and it taught what was happening in the myocardium. It taught that it was the energy content of the heart muscle and not what one heard that was of importance. Many a useful young man had been thrown out of the army because he had a murmur in the second left pulmonary space. Such a murmur was found in many children and chiefly in vigorous young adults. This murmur was caused by the cornus arteriosus rubbing against the chest well because the lung was not big enough to cover the heart, and the murmur frequently disappeared when the lung was expanded. After a child had had an attack of sepsis or endocarditis, one could judge by this method whether that individual child could take a certain amount of exercise. Mitral stenosis was more common in girls than in boys because when the mitral valve was involved a boy was not so easily controlled and broke open the slight adhesions that formed at the base of the valve, while a girl was afraid of overexerting herself and the mitral valve closed at its base.

Dr. MAUD LOEBER of New Orleans emphasized that Dr. Wilson had given them a definite guide so that they could know just what to do in regard to giving children permission to take exercise. This would be of particular value in schools or gymnasiums. The test used most frequently had been to go by the pulse rate, but this work had introduced an entirely new idea and would make them review the methods they had been using in permitting children to enter competitive tests and games. This test put the physician in a position where he could do justice to both the conscientious mother and the active child.

Dr. WILLIAM ST. LAWRENCE of New York stated that Dr. Wilson had confirmed the work of Barringer, Rapporte, and Lewis. These curves which she had demonstrated were sufficiently accurate for clinical purposes; however, their interpretation was still a matter of judgment. Dr. Wilson had studied these curves in cardiac children and had treated children by graduated exercise with the methods of Lewis, and had found them of considerable use within rough limitations. Her precise methods, however, were more satisfactory and would be a great addition to the subject.

Dr. DEBUYS of New Orleans also commended Dr. Wilson on her very excellent piece of work and agreed that it would be of a great deal of assistance in guiding the exercise of school children. A piece of work like this would undoubtedly help along in a field which offered such immense possibilities.

Dr. TALBOT also congratulated Dr. Wilson on her paper, more particularly because it was a study of the normal and because it was by the study of the normal that pediatrics would be advanced. Although he had made no actual measurements, he thought what she said of the child applied also to the infant from certain observations that he had made during metabolic experiments in infants.

Dr. F. C. FLEISCHNER of San Francisco, after congratulating Dr. Wilson, said that the important feature in all this work was that it was one more point indicating that the main thing in the observation of cardiac cases was the appearance of the child. He hoped in closing the discussion she would make mention of the color of these children. As one watched the cardiac child he was struck by the fact that frequently the effect of exertion was indicated by the color of the child. Another point was how they would be able to make mothers graduate the exercises properly in normal children. Many mothers showed no judgment in regulating the amount of exercise for their children and many young children were unduly fatigued because the inclination of the nurse rather than the exercise tolerance of the child was the guide as to the amount of exercise the child took.

Dr. WILSON, in closing the discussion, stated that she was now interested in exercises for cardiac children, and had been particularly impressed by how much many of these children could do and how little we had appreciated this fact. The curve demonstrated was not exact and to be followed by itself, but was a check on personal observation. One should observe the symptoms of overexertion in normal children and check up on his own judgment and then this method would be found to be of practical value. She had found it a good plan to do this work with the mothers present, for when they saw the work they were convinced and were willing to follow directions. When the children reached about the limit of tolerance they became flushed and when overworked presented a grayish hue.

Intubation of the Larynx.—Dr. HENRY J. CARTIN of Johnstown, Pa., presented this paper in which he reviewed a former communication reporting 317 cases of intubatino in laryngeal diphtheria. He had now collected additional cases, bringing the number up to 440. The mortality was 14.5 per cent. He made a plea for a more careful diagnosis, as he believed that many cases of so-called croup were cases of laryngeal

diphtheria, and urged the early administration of antitoxin in large doses. He gave twenty thousand units as the initial dose. Most of these intubations were performed in homes of the poorer class, where all facilities were lacking. He formerly had operated only when stenosis threatened life, but after several losses had concluded that it was better to operate early and he began to operate when there was beginning dyspnea. Some of the cases at that time might have recovered without operation, but he thought it safer not to take the chance where these children were in homes and not under the constant supervision of the doctor or nurse. On the other hand, no case was too far gone to be deprived of the chance for life that intubation might offer. The operation required skill and dexterity. He used the O'Dwyer hard rubber tubes and operated with the child in the dorsal position. After the operation the string was removed. He used rather large-sized tubes and had not found that they caused paralysis. The tube was usually removed on the fifth day. In this series of cases there were no chronic cases and no tracheotomies. Where reintubation was necessary it was usually within the first two hours following the introduction of the tube. After a detailed analysis of these cases, Dr. Cartin concluded that the low mortality, 14.5 per cent., was due to early intubation and large doses of antitoxin.

Dr. Isaac Abt of Chicago said he had had the privilege of hearing Dr. Cartin's former paper in 1917 and at that time was very much impressed with the work he was doing and with the success that attended it. This operation was not being performed as frequently as it formerly was because children were receiving antitoxin earlier and there was not so frequent need for it. Dr. Abt called attention to retraction of the intercostal muscles and retraction at the end of the sternum and upper portion of the manubrium as evidence of laryngeal stenosis. There were, of course, minor degrees of stenosis in which this picture might not be so marked. If the patient was in a hospital where he could be watched by an interne one could wait a reasonable length of time before operating, but where the patients were distributed over a wide area and more or less inaccessible one could stretch the indications for intubation. Everybody was not master of the technic as Dr. Cartin was and as Dr. Cartin had suggested intubation was becoming a lost art. The younger men knew very little about the operation or the technic. He had rarely intubated with the patient in the recumbent position, having preferred the vertical position advocated by Dr. Northrup. In using tubes of large size it must be remembered that the trauma inflicted was greater in proportion. There were rare cases in which it was impossible to intubate. Several of these were recorded in the literature.

Dr. L. T. Royster of Norfolk, Va., stated that he had had an average of about 13 cases requiring intubation every year for the past twenty years. In every community there should be one expert intubator. With proper assistance an expert should be able to perform the operation in ten seconds, and very rarely should he have to make a second attempt. He also felt that it was better to intubate early, even unnecessarily, rather than wait until too late. Many of these children did not die of diphtheria septicemia but of cardiac failure because of the additional work thrown upon the heart because it was compelled to work against a stenosed larynx. It was well never to take chances with a case of croup unless one was certain that it was a catarrhal and not a membranous croup. It was better to do a tracheotomy than to intubate the same patient eight or ten times. One should never allow the child to become cyanotic before intubating. He cited a case in which it was impossible to intubate because of a chondroma of the larynx growing downward.

Dr. A. J. Scott of Los Angeles stated that in their county hospital service they had two or three cases of laryngeal diphtheria every month and the internes got the benefit of the intubations because the attending physicians lived too far away. A great many of the cases came in almost moribund and during the attempt at intubation it became necessary to do a tracheotomy. The point he wished to bring out was that laryngeal diphtheria started out like croup and the parents did not pay any attention to it and neither did the physician. In giving antitoxin he never gave an initial dose of less than twenty thousand units when there was a beginning laryngeal stenosis, and he preferred to make the injection in the vastus externus, high up.

Dr. George Dow Scott said he had seen many of these cases when he formerly practiced in Boston and there were many at the Willard Parker Hospital in New York. Dr. Cartin's results were certainly magnificent. The cases they saw often came in late and often developed bronchopneumonia and they could do nothing with them. They also had many chronic cases in which the children continued to wear the tubes for a long time and could not speak. They now felt that the only effective way to give antitoxin was intravenously. Both Dr. Cartin and Dr. Royster had mentioned that they had never seen a case of laryngeal diphtheria in a negro. He had seen only one case but that was not intubated.

Dr. John A. Foote of Washington, D. C., said the negro did get laryngeal diphtheria and did have to be intubated. However, the number of cases was not proportional to the population. Another point to be emphasized was that intubation was the work of the physician and not of the laryngeal surgeon. As to finding someone to do this work, it was quite possible to train any physician to do this work; he had even trained a nurse to intubate with great dexterity.

Dr. Wilson of New Orleans said he had changed his opinion many times during twenty years and one point on which he had changed his mind was as to the length of time the tube should remain in place. There were different opinions on this point in different countries. In France they left the tube in only twenty-four to forty-eight hours. He agreed with Dr. Cartin that five days was about the correct time. Dr. Wilson said he never intubated with the child in the recumbent position.

Dr. Cartin, in closing the discussion said he believed Dr. Scott's location for injecting the antitoxin was better than his own. Dr. Scott had spoken of having a number of chronic tube cases in the hospital. In his opinion a chronic tube case was the result of trauma, though he might be wrong. He was formerly afraid to remove the string but after having had two accidents as the result of leaving it he now always removed it. He could not agree that intubation did not belong in the domain of the throat man. He did not always remove the tube at the end of five days. Sometimes he removed it at the end of two days and in other cases he had left it in as long as fifteen days. One of the speakers had advised practising intubation on the cadaver; in the cadaver there was no tension of the parts. He suggested getting a fairly large dog instead.

Third Day—Friday, April 30

Observations on Tumors of the Kidney in Children.—Dr. William E. Carter and Dr. Langley Porter of San Francisco made this presentation, in which they classified tumors of the kidney in children as follows: (1) Malignant tumors—sarcoma, adenosarcoma, teratoma, sarcocarcinoma. (2) Benign solid tumors—lipoma, chondroma, osteoma, fibroma, adenoma. (3) Cysts—congenital cystic kidney, hydronephrosis, pyonephrosis, hydatid cysts. The greatest number of cases of tumor of the kidney in children occurred between the sixth month and the sixth year of age. In going over the records of three hospitals and their private cases they had collected 12 cases of tumor of the kidney in the past five years. These all occurred in children under seven years of age. There seemed to be nothing in the histories of the pregnancies and labors to explain them. The most distinctive physical signs of tumor of the kidney in children were fulness at the costal vertebral space and at times intermittent hematuria. Tumor of the kidney might be confused with tuberculous peritonitis, but usually fulness at the costal vertebral angle served to make the differentiation. Other symptoms and signs were asthenia, pain, presence of varicocele, Lucas-Championnère, sign, secondary blood changes, and digestive disturbances. Kidney tumors were differentiated from adrenal cystoma by the eye symptoms. Frequently metastases occurred early and were sometimes observed before the original

growth made itself manifest. The treatment was surgical. The twelve cases were reported in detail.

Dr. L. T. LeWald of New York reported one case of kidney tumor in a baby six months old in which there was a hydronephrosis and referred to two other cases of cystic kidney in babies, all of which were operated upon successfully, though the impression was given by a urologist and other physicians who examined them that they were inoperable.

Sir Humphrey Davy Rolleston expressed his admiration for the paper of Drs. Carter and Porter, which he said showed not only a very extensive acquaintance with the literature of this subject, but a great deal of personal observation. He then discussed the difficulties surrounding the study of the pathology of tumor kidneys in children and their classification, referring particularly to the difficulty of determining in some instances whether the tumor was of embryonal origin, and of drawing the dividing line between sarcoma and leucemia before the blood changes became marked. He also spoke of rabdomyosarcoma, which he said had impressed him as being very rare in children. He had never come across a kidney tumor in a child containing striated tissue. In discussing the clinical aspects of kidney tumors in children he pointed out that the position of the colon, in front of or below the kidney, might be of aid in differentiating between renal and adrenal tumors. In malignant tumors producing secondary growths often the first symptoms appeared in the eyelids, and eye symptoms pointed to a tumor arising from the medulla. There was also an interesting group of tumors arising from the cortex which gave rise to one or two changes. There might be a precocious growth of hair or a change in the muscle tissue with a deposit of fat infarcts, producing the infant Hercules type. In connection with tumors of the cortex, another interesting point was that the question had come up whether they might not arise from bits of embryonal adrenal tissue in the kidney cortex, and if such was the case whether they were not comparable to tumors arising from the adrenals.

The Temporary Teeth: Disorders Due to Their Neglect.—Dr. J. Ross Snyder of Birmingham, Ala., read this paper. He declared that pediodontia was still in its infancy but merited culture and development. The care of the child's teeth was a subject that until recently was ignored by the pediatrist and neglected by the dentist. The dentist was not altogether to blame if he gave more attention to the apparently more urgent and more lucrative demands for his services from adults. The majority of dentists had neither the time nor the inclination to treat temporary teeth. The early care of the child's teeth was a matter in which the pediatrist should assume greater responsibility. It had been estimated in New York that 98 per cent. of all teeth were perfect when they emerged from the gums and that by the time the children reached the first grade in school 98 per cent. of them had bad teeth, and one-third had abscess conditions. Equally bad conditions had been revealed by the inspection of the mouths of school children elsewhere. Much time was spent in the preparation of the food supply so that it should be free from contamination and properly prepared, yet when it passed through a neglected mouth it might become infected and give rise to gastrointestinal disturbances. In the presence of an unclean mouth infection occurred more easily. The premature loss of the deciduous teeth was the most frequent cause of malocclusion and deformities of the face and jaws. There was great need in every community of education as to the need of early dental hygiene and prophylaxis. The education of parents in this matter could not be left to the dentist but was a responsibility which the physician, and particularly the pediatrician, should assume.

Dr. Julius P. Sedgwick of Minneapolis said he was very glad to hear this paper, for frequently they had cases which were obscure in which the diagnosis was cleared up by examining the teeth carefully. He cited an instance of one child sent from Oklahoma to Minneapolis to recover from malaria. This child's teeth were properly cared for and the malaria disappeared. They had in their children's clinic attached to the University a dentist who cared for the children's teeth. In their private clinic they also had a dentist, and they found that many times he helped to make the diagnosis in obscure cases. As to the prophylaxis, Dr. Snyder was quite right; children should be sent to the dentist early and regularly.

Dr. Isaac Abt of Chicago called attention to the fact that more dentists now hesitated to extract the temporary teeth because if they were removed there was no room left for the eruption of the permanent teeth, and malocclusions and deformities resulted. In addition to what had been said of the influence of proper feeding on the teeth there were other diseases of infancy that had an effect on the teeth later on. Tetany in infancy might be responsible for poorly developed teeth, enamel erosions, and lamellar cataract. The question was one which deserved further consideration. He suggested that some of the men who had the opportunity to see a number of children study the relation of malocclusion and other dental conditions in relation to constitutional states, growth, nutrition, development, blood conditions, etc.

Dr. C. H. Wahrer of Fort Madison, Ia., asked what was to be done when the dentists took the stand that they had in his State. There the State Dental Association had gone on record as saying that the dentists were not going to take orders from the physician because they knew more about dentistry than the doctors. At one time the idea that the teeth were responsible for all sorts of diseases was ridiculed and now perhaps the physician had gone too far to the other extreme, but between the extremes lay much truth, and by the use of good judgment one could certainly arrive at the truth.

Dr. L. R. DeBuys brought out the point that the care of the teeth should begin when the first tooth erupted. Too frequently parents waited for the appearance of several teeth before they began to use the tooth brush. Another point that had impressed him was the slightly elevated temperature found in the mouths of those who had dental caries over a long period. In such cases the mouth temperature should be disregarded and the rectal temperature employed.

Dr. Fritz B. Talbot said Dr. Abt had spoken of a case of tetany having poorly developed teeth. The recent work of Howland on the blood calcium showed that the blood contained a diminished amount of calcium during the acute stages of certain diseases. There was a direct relation between the teeth and digestion, and there was scientific proof that the digestion had a great deal to do with the teeth.

Dr. E. C. Fleischner of San Francisco suggested the axiom "Every tooth is either good enough to fill or poor enough to pull." A carious tooth corresponded to a sequestrum of bone in another part of the body and should be treated on the same principles as such a sequestrum would be treated.

Dr. Snyder, in closing the discussion, emphasized that the physician should not condemn the dentist until he had taken a little more care himself.

The Coagulation Time of the Blood in the New-Born with Special Reference to Cerebral Hemorrhage.—Dr. Frederick C. Rodda of Minneapolis read this paper in which he stated that his interest in this subject had been aroused by autopsy findings. In the post-mortem examination of infants dying of cerebral hemorrhage over 50 per cent. had been found to follow non-instrumental deliveries and many followed normal and easy births. In these cases the blood was found slightly or not at all coagulated. He had also been struck by the fact that cerebral hemorrhage was by far the most frequent cause of death in the new-born. In many cases at post mortem no torn veins were found in the cerebrum or cerebellum to account for the hemorrhage and multiple hemorrhages in these cases were found in portions of the body where it was inconceivable that they could be explained by trauma. Over 25 per cent. of all infants dying of cerebral hemorrhage showed this picture of multiple hemorrhages. An analysis of cases reported in the literature deepened the conclusion that these hemorrhages were due to factors other than trauma. Further study led to the conclusion that there was a disturbance in the coagulation time of the blood in the new-born. It was found that the average coagulation time in the new-born was seven minutes. (*American Journ. Diseases of Children*, April, 1920.) In some

infants the bleeding time was prolonged. In icterus, melena, jaundice, syphilis, and non-traumatic cerebral hemorrhage, the coagulation time of the blood was prolonged. In melena it might be delayed to ninety minutes. In these cases the subcutaneous injection of normal blood was effective in cases in which there was delayed or slow bleeding. A careful study of the blood and spinal fluid was made in cerebral hemorrhage and it was found that the average clotting time was 13 minutes; in one case, on the first day it arose to 90 minutes and after transfusion dropped to eleven minutes. Where the blood clot could be localized in the brain as was sometimes possible, operation was justifiable.

Dr. ISAAC ABT of Chicago said they were accustomed to think of cerebral hemorrhage as the result of trauma and frequently the obstetrician was blamed for damage for which he was not responsible. Dr. Rodda had brought out the most frequent cause, and the reasons for it. This contribution to their knowledge should be helpful in the clinical management of these cases. It showed the importance of ascertaining the coagulation time of the blood in babies that showed a tendency to bleed. If one could detect oozing by estimating the coagulation time of the blood extensive hemorrhage into the meninges might be prevented in many instances. If one recognized that there was slow oozing into the subdural or subarachnoid space an injection of blood might be made into the muscles or a transfusion into the longitudinal sinus. Another point of importance was that surgery in some cases was successful, and when one considered the severity of these cases, if the seat of the hemorrhage was localized it was quite possible that surgical interference was justifiable, if not indicated. If nothing else was done a decompression to relieve the pressure on the cortex might be advisable.

Dr. JOHN A. FOOTE of Washington, D. C., considered this work of Dr. Rodda's of great importance and particularly so when one took into consideration the influence of infant mortality at the time of birth on the general infant mortality rate, and the fact that 50 per cent. of the infant deaths during the first month occurred during the first two days of life. The condition described by Dr. Rodda was found in a large number of cases in routine autopsies where no symptoms had been present so that a standard and rapid method for obtaining the coagulation time of the blood would be very useful. He had found it necessary in some cases to use thromboplastin and he had used blood transfusion with good results.

Dr. H. B. HAMILTON of Omaha, Neb., said it had been his good fortune to see some of Dr. Rodda's work and he felt that it would be a great aid not only in reducing infant mortality but in lessening the morbidity, the physical deformities and perhaps the deformities of mental and moral character that followed a failure to recognize and treat these cases of cerebral hemorrhage. He had seen some cases of cerebral hemorrhage due to the use of pituitrin by the too enthusiastic obstetrician. In cases associated with intracranial pressure it might be necessary to resort to extreme measures. If the hemorrhage was localized he thought it was sometimes justifiable to operate. Some one had suggested repeated lumbar punctures where the hemorrhage was localized and the question of opening the cisterna magna had been discussed. This he felt was rather a formidable procedure, but possibly even an unsuccessful operation was preferable to the condition in which some of these children had to live.

Dr. RODDA, in closing the discussion, again emphasized the frequency with which cerebral hemorrhage occurred and the difficulty of explaining it where labor had been normal. Lumbar puncture might give good results if the bleeding occurred below the infratentorium. In discussing the possible causes of delayed bleeding, he said he had noticed in taking blood for the purpose of estimating the coagulation on time, that if the little clot that formed after the withdrawal of blood was brushed off fresh bleeding occurred; it was possible that after such a small clot had formed in the brain of an infant crying or vomiting might dislodge the small clot and start fresh bleeding. Surgery to be effective should be done early and before it was undertaken a transfusion should be done. If, however, operation had been delayed for fourteen days it was not necessary to give a transfusion.

The Antiscorbutic Value of Proprietary Baby Foods.—Dr. JOSIAH J. MOORE of Chicago described feeding experiments with white mice and guinea pigs in which various proprietary infant foods were employed. The proprietary foods employed were divided into two groups, namely, those that were supposed to be complete foods without the admixture of milk, and those to which cows' milk was added. Certain of these foods were found sufficient for the maintenance of white mice but were inadequate in antiscorbutic properties when fed to guinea pigs. Frequently the animals gained rapidly for a short time but they all developed scurvy later. The only difference noted between the foods that were modified with milk and those to which no milk was added was that scurvy appeared earlier when the latter class of foods were used, but they all eventually succumbed. It was observed that the foods modified with milk induced more rapid growth than those not thus modified. It was also found that normal adult guinea pigs did not develop scurvy on these diets as soon as did young, growing animals. It might be argued that the findings in guinea pigs did not form a criterion as to what would happen in the human infant, for it was known that the guinea pig required more antiscorbutic food than the infant, but the experiments were suggestive and confirmed the findings of other investigators as to the need of antiscorbutic food for infants. All infants receiving proprietary foods whether or not modified by the addition of cows' milk should receive an antiscorbutic.

Dr. JULIUS HESS of Chicago said he had had occasion to follow some of Dr. Moore's work and he regretted that one part of the work was not sufficiently near completion to be reported. He had been verifying some of the work done by Dr. Hess of New York. The work was done on guinea pigs, though this animal was far from ideal and the results could not be definitely compared with the results in the human. Unless the guinea pig was fed considerable roughage it had intestinal stasis and this had a profound influence on scurvy, and then too the guinea pig was very susceptible to infection. In the foods not containing milk the shortage was not in one only but in several elements and unless milk was added they were by no means complete foods. Manufacturers knew this and these foods were not put on the market as complete foods but most of them while calling for the addition of milk did not advise the addition of sufficient milk and did not make provision for an adequate amount of antoscorbutic food to guard against the milder forms of scurvy. Antiscorbutics should be given to infants earlier than most writers advised, and if a proprietary food was used the child was susceptible to scurvy much earlier than if cows' milk were fed.

Studies of the Effect of Diphtheria Toxin on the Heart.—Dr. HUGH MCCULLOCH of St. Louis read this paper in which he stated that it was a well recognized fact that during the course of infectious disease in childhood certain changes in the heart muscles occurred due to the action of toxins. Diphtheria toxin acted on highly specialized tissue in the body producing parenchymatous degeneration with secondary interstitial changes. A very important effect was on the heart muscle. This action was not a local infection, but an action of toxins on the muscle cells. Occasionally at autopsy they found a case in which these changes in the heart muscle could not be demonstrated and yet these children during life had shown the signs of myocarditis. They felt that in such cases functional changes must be responsible for the acute cardiac failure, breathless, and cyanosis which was observed. A study of this question led to the conclusion that the effect of the toxin might be on the whole heart muscle or on the structures controlling the rate and propagation of the impulse from auricle to ventricle and through the walls of the ventricles. Experiments had been carried out on animals to show the effect on the heart under such conditions and electrocardiographic tracings had been made. The conductivity might be interfered with at any point along the path of the impulse, giving rise to auricular flutter, paroxysmal tachycardia, or ventral fibrillation. The electrocardio-

graphs frequently showed a change in the ventricular complex. The essayist presented an analysis of a series of 80 cases. Those cases in which the muscle alone showed changes might recover provided the cardiac reserve was preserved. It seemed that functional changes rather than organic were responsible for some of the cardiac conditions seen in diphtheria and it seemed altogether probable that these conditions led to chronic cardiac disease subsequently in life.

Dr. FREDERICK C. RODDA of Minneapolis emphasized the point that it was the diminution of the cardiac reserve that was responsible for the fatal ending in so many of these cases. He felt that the application of the electrocardiograph to the study of cardiac disease in children would show a great deal in the future with relation to heart diseases due to other causes than dipththeria.

Dr. TALBOT of Boston said that when any new method came into use it took many of them some time before they could understand the technicalities that must be mastered before they could make use of it, and there was no doubt but that by the use of the electrocardiograph they were receiving a great deal of new knowledge which would be of the greatest value in the recognition and treatment of cardiac conditions. It was a valuable thing which the future would bring into greater and greater importance.

Intramuscular Blood Injections as Nutritional Aids.—Dr. THOMAS D. PARKE of Birmingham, Ala., reported four cases of ileocolitis in which nourishment and even water could not be retained when given by mouth. These cases were treated by hyperdermoclysis and intramuscular injections of citrated blood administered daily, the average injection being 10 c.c. of blood. Although these cases were too few to warrant definite statements he felt that the blood injections had been responsible for tiding these children over a critical period until feeding by mouth could be resumed. Where many injections had to be given it was sometimes difficult to find a muscle. He had made injections into the pectoralis, the hamstring muscles, and the gastrocnemius. Fifty c.c. was the largest amount given at one injection.

Dr. FRITZ B. TALBOT of Boston said it was well to bear in mind that there were a great many things that played a part in the recovery of a child. Among these was the fluid intake and output of the body. The fluid output in cases of diarrhea was extraordinarily great. It was surprising how much could be lost in twenty-four hours and if nothing was going into the body a great deal of tissue was being lost. Great emphasis should be placed upon giving enough liquid in these cases to maintain the body.

Dr. PARKE, in closing the discussion, said he was glad Dr. Talbot had called attention to the water intake, for that was most important. In these cases he gave injections of normal salt solution, six or eight ounces at a time.

Local Anesthesia in Infancy and Childhood.—Dr. ROBERT E. FARR of Minneapolis presented this contribution which was illustrated with lantern slides. He said he thought it was quite generally known and appreciated that novocaine was the safest anesthetic known, therefore if one could use novocaine he should not use a more dangerous drug. It was also known that many children were in a bad condition following the use of a general anesthetic, and that the nature of the anesthetic often decided the issue. The psychological effect did not play as important a part in local anesthesia in children as it did in adults. The illustrations showed how the child could be restrained on an arm table set at right angles to the operating table. The child's feet were attached by bandages to the operating table, and the nurse held the arms above the elbow. In this way children even several years old could be held quite well. As a rule the child needed restraint only while the anesthetic was being given. They had been doing many different kinds of operations under anesthesia. Recently they had been using local anesthesia in operating for harelip and for abdominal operations. The apparatus for giving the local anesthesia was very simple. They were always prepared to reinforce the local anesthesia with general anesthesia; but it was rarely necessary to do this. The infiltration was made beneath the skin and when the reflexes were abolished abdominal operations could be performed without extrusion of the viscera. Local anesthesia was particularly applicable to operation by the Rammstedt method for hypertrophic pyloric stenosis. If there was pain the procedure could not be called anesthesia. Dr. Farr reported a series of 129 cases of children operated under local anesthesia and in only nine was there any pain; when this occurred it was due to an error in technique. The operation for hypertrophic plyoric stenosis could be done under local anesthesia in 12, 15, or 18 minutes, and with the danger of a general anesthetic eliminated it was possible that borderline cases might come earlier to operation. The solution used was a 0.6 per cent. solution of one per cent. novocaine in Ringer's solution.

Dr. MARTIN B. TINKER of Ithaca, N. Y., expressed the opinion that local anesthesia in children was a life-saving procedure. He said he had been enthusiastic over it for many years. The patients in whom local anesthesia was used were surprisingly free from the after effects that were present in general anesthesia, and it was generally conceded that children took a general anesthesia poorly. He had amputated two fingers with local anesthesia and the patient was perfectly satisfied. The point to be emphasized was that any local anesthesia that was not satisfactory to the patient was not local anesthesia. If the child struggled and cried that was not anesthesia at all. It was understood that a general anesthesia should be given at any time if the local anesthesia was not satisfactory. Another advantage in the use of a local anesthesia was that the surgeon was more likely to handle the tissues gently and that was even more important in children than in adults. In hypertrophic pyloric stenosis Dr. Bevan and other surgeons in the surgical section had favored the use of local anesthesia, and thought that a general anesthesia should not be used in these cases. Still another point in favor of local anesthesia was that the loss of blood was less than with general anesthesia. Local anesthesia was unquestionably the anesthesia of choice if the child was not of the nervous type, but in children from two to seven years of age who were nervous there might be some question whether the shock from the local anesthesia was not greater than from a general anesthetic. However, as a rule, the nervous shock was greater from general than from local anesthesia.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

REPORT OF THE PHILIPPINE HEALTH SERVICE For the Fiscal Year from January 1 to December 31, 1918. Prepared under the Direction of VICENTE DE JESUS, M.D., Acting Director of Health. 332 pages. Published by Manila Bureau of Printing, 1919.

CANCER COMMISSION OF HARVARD UNIVERSITY. Seventh Annual Report of the Collis P. Huntington Memorial Hospital for Cancer Research and of the laboratories of the Cancer Commission of Harvard University, 1918-1919 (for the Year Ending June 30, 1919). 59 pages. Published at Boston, Mass.

THE TREATMENT OF SYPHILIS By Dr. H. SHERIDAN BAKETEL. 167 pages. Published by The Macmillan Co., New York.

DISEASES OF THE CHEST AND THE PRINCIPLES OF PHYSICAL DIAGNOSIS. By Dr. G. W. NORRIS, and Dr HENRY R. M. LANDIS. 844 pages. Published by W. B. Saunders Co., Philadelphia, Pa.

PASTEUR, THE HISTORY OF A MIND. By EMILE DUCLAUX. 363 pages. Published by W. B. Saunders Co., Philadelphia, Pa.

AUS 25 JAHREN ORTHOPÄDISCHER ARBEIT. By Dr. OSCAR VULPIUS. 80 pages. Published by Urban & Schwarzenberg, Vienna.

THE EVALUATION OF RECENT INVESTIGATIONS CONCERNING THE WATER METABOLISM OF THE BODY IN RELATION TO THE DIGESTIVE SECRETIONS AND THE FUNCTIONS OF THE BLOOD.

BY JOHN C. HEMMETER, M.D., PH.D., SC., LL.D.,

BALTIMORE, MD.

BEFORE going into the subject of the rôle of water in the metabolism of the body, it is necessary to ask the question *"What is water"?* It would be easy to answer that it is a liquid substance of a formula OH_2 and that by a suitable apparatus a weighed quantity of water may be split up into two parts of hydrogen and one part of oxygen, the resultant separated gases having the total weight of the original quantity of water used.

Ordinarily such an answer would suffice; but physical chemistry and physiologic chemistry have broadened our views concerning the structure of water. It may be regarded as a mixture of units of varying molecular complexity. This interpretation is now widely accepted by physical chemists. These units may be expressed by the following formulas (OH_2), $(OH_2)x$, $(OH_2)y$.

This fundamental unit (OH_2) is designated as as "hydrone." Water, however, cannot be a mere assemblage of molecules which are all alike and which are represented by the conventional formula OH_2; this is fictional water and actual dry steam. In dry steam the individual separate physical units are, for the most part at least, molecules of this simple order of complexity.

The simplest constituent of water may be termed "hydrone." Water, it may be supposed, consists of hydrone in admixture with various polyhydrones formed by the association of two or more molecules of hydrone. How many of these and what the limit of association may be, we do not know and cannot say at present. The state of water, even at steady temperatures, must be one of constant flux, of oscillatory change from form to form about a point of equilibrium. Any interfering substance introduced into the turmoil, it must be supposed, will disturb this equilibrium—presumably in the direction of an increase in the proportion of the simpler molecules; and as the simpler molecules are the more self-attractive, the liquid complex would tend, if opportunity were given, to attract such molecules to itself from outside until equilibrium were restored.

In a recent address by Prof. Henry E. Armstrong, Cantor lecturer to the Royal Society of Arts, England, March 31, 1919, he states that hormones act mainly by causing disturbances in water, and as we are composed largely of water, changes producible in water may concern us very closely. The extent to which water enters into the composition of the various organs of our body, will be brought out in the following portions of this communication.

It will have to be added that enzyme action in the living body is impossible in the absence of water; in fact, all chemical action requires the presence of water, and even where we would least conceive water to be playing a rôle; for instance, during the process of incineration, for here the first steps in the process consist in the separation of the water which is not detectable by our senses, as a rule.

This article is not a communication of an original research, but as the researches concerning this subject have become so large in number that their application to the understanding of life processes has become difficult for reason of the very largeness of their number, a sifting of the experimental bio-chemical results and their application to the various functions of the human body is necessary, and may become necessary every few years. Otherwise, we shall become lost in a mass of detailed experimental results, each conclusion being isolated as long as it is not fitted into the synthetic structure of physiology.

The authors from which I have quoted are given in the text.

Water metabolism as such is not dealt with as a subject by itself in any of our modern text-books on physiology, which refer to it under such headings as "absorption," "digestion," and the "passage of dissolved substances through membranes," etc.

It has now become necessary to have perspective of the entire subject of water metabolism, irrespective of the single or special function which water may perform in one or other of the many life processes. Some of the results of research on water metabolism may be found in such books as Macleod's "Physiology and Biochemistry in Modern Medicine" and Lusk's "The Science of Nutrition." H. J. Hamburger's book entitled "Osmotischer Druck und Ionenlehre in den medicinischen Wissenschaften," has been a mine of brilliant and valuable investigation containing the proof of basic principles of osmosis that can be found in no other work. Otto Cohnheim, "Die Physiologie der Verdauung und Ernährung," presents the matter of water metabolism as it concerns the digestion in such a masterful manner, and gives so many excel-

lent references, that I have quoted him literally in many places.

Water Metabolism.—Blood, lymph, and tissue fluids are solutions in water. Living protoplasm also consists chiefly of water. In the case of muscles, various measurements show that they consist of approximately 78 to 79 per cent. water. As furthermore the muscle contains solid supporting fibers, it follows that contracting tissue itself has a still higher percentage of water. The glands consist of matter more solid; in the embryonic organism, which lacks supporting tissue, skeleton and fatty tissue, the percentage of water reaches almost 90. The percentage of water in protoplasm, then, may be said to be between 80 and 90. H. Bischoff and Voit state that the average percentage of water in man is 60; lean people have a little more; stout ones somewhat less. More than half is contained in the muscles. The percentage of water in the body is not the same at all times, but at different times it varies considerably. This, however, is not the case with blood or the actual protoplasm, but rather with certain water reservoirs of which I shall soon have to speak in detail. The percentage of water in the body depends much upon whether these are filled or empty.

Water is brought into the body: (1) by drinking, (2) by absorption of water contained in solid food, (3) through formation of water when the hydrogen of food stuffs is oxydized.

Water leaves the body: (1) in urine, (2) in feces, (3) in the water vapor from the lungs, (4) in the perspiration from the skin.

Besides these, the body has an intermediary water-movement, which, as a rule, considerably exceeds the total circulation. This first is the secretion and then the resorption of the digestive juices. We are not well informed as to whether an active exchange of water takes place between blood and tissue, and among the tissues themselves, perhaps between the cells and the tissue fluids. The lymph which streams back into the blood through the thoracic duct seems in the case of man to amount to about 2 or 3 liters per day.

The amount of water which a man takes in during a day in his food and drink varies greatly, as it is determined essentially by the amount of perspiration which he produces, and this depends upon the muscular work and the temperature without. People who live under normal conditions and who are moderately active, says Forster, take up 2215 to 3538 grams of water a day, and 288 to 468 cm. of oxydized hydrogen must be added. Vozarik's figures are similar.

In the last few years, Chittenden, Atwater, and Benedict have made numerous experiments in America, where people as a rule are lighter and thinner, and their results are somewhat lower—1250 to 3000 cm. Chittenden even had cases of 660 to 900 cm. a day where there was little food and slight bodily exercise. In the case of the large figures, we must not forget that many fluids are taken for pleasure, and much more is taken into the body than it actually needs. People who drink much beer seem to require more water when they abstain. Bodily exertion, especially in hot weather, when much is demanded from the physical regulation of temperature, brings the daily consumption of water up to many liters a day. Atwater and Sherman noted water-consumption of more than 8 liters a day in the 6 day cycle races; there may be still more in over-exertions in the hot sun. In cases of diabetes insipidus and developments from injuries to the head there has been observed a water-consumption of more than 20 liters per day, which the organism receives without harm.

It is important to discover the total amount of water which the body circulates, but still more important to see in how short a time our organism can receive large quantities. You all know how much water one can pour down when very thirsty; and you know from your own experience, or from observing other people, that to manage 3 or 4 liters of beer is rather a matter of minutes only. What becomes of it all? It is known that pure water passes quickly through the stomach (*Cohnheim's "Rinne"*) whether it be filled or empty. The fate of the various drinks is not known to us, but those that are very dilute will scarcely act differently from pure water; when there is much sugar, it may happen that resorption is somewhat delayed. Water, sugar, and the salts contained in milk also are quickly absorbed. Thin soups quickly leave the stomach. In the case of thicker soups and broths, a separation probably takes place in the stomach which lets the water pass off rapidly. Fluids, therefore, never gather in the stomach, and the small intestine is always quickly emptied. Even the greatest quantities of water which the organism takes up in a short time pass through at once into the secretions, excretions or water reservoirs.

The body in turn can reabsorb from the secretions considerable quantities of water in a short time.

The water which leaves the body in the feces normally plays but a small part—perhaps 100 g. per day. The water discharged through the urine is figured on the average as 1200 to 1500 c.c. This is essentially a secondary process which depends on the presence of diuretic substances, through which the superfluous water is removed from the body. It may amount to several liters when beer or tea have been taken, but may shrink to 466 c.c. and also less, when the food contains little nitrogen and salt. The kidneys are able to excrete great quantities of salt and urea in case very little water is taken in food, etc., or when this has been reduced through sweating. In a manner largely independent of its physiological processes, the body emits water through the lungs. The air which is breathed is generally of lower temperature than the body and not entirely saturated with water vapor; it is heated in the lungs to 37° C., and is nearly saturated as it comes in free contact with the moist surface of the lungs. The climate, therefore, is the chief determining factor in the secretion of water through the lungs, and only muscular work with its consequent increase of the expansion and aeration of the lungs somewhat increases the amount of water excreted. It is estimated that in man about 300 g. of water a day evaporate through the lungs. Zuntz and Schumburg estimate 108 to 274 g. of water excreted through the lungs according to the atmospheric conditions during a march of 6 or 7 hours, covering 25 km. with

infantry pack. There may be more in mountain climbing; it has not been determined what the due influence of a lower barometric pressure is upon the exhalation of water vapor.

The excretion of water in digestion and sweat meets urgent demands of the body. There is far more water in the digestive secretions than has formerly been supposed. A man in one day secretes about two liters of gastric juice, about one and a half liters of saliva, one to one and a half of pancreatic juice, and a considerable amount of intestinal fluids—altogether about six liters or more of digestive juices with about 11 g. chlorine. If you reflect that man has only three liters of blood serum with perhaps 10 g. of blood chlorine, you can see what demands are made of his organism in the provision of this quantity of water and salt. Although the secretion requires many hours, and the water and the hydrochloric acid secreted in the stomach rapidly pass from the small intestines back into the blood, yet one can easily prove on dogs that the process of secretion suffers considerably when the body lacks water. It may even happen in experiment with animals that a diet of meat is not dissolved in the stomach, but lies long undigested, and then passes the pylorus but little changed. We all are familiar with the ceasing of the salivary secretion during violent thirst.

But the most important function of water in the whole organism is the part it plays in regulating the physical temperature. It is a matter of common knowledge than when the temperature of the body threatens to rise above the normal height, the water evaporates and then cools the body, cooling by evaporation. This evaporation takes place on the skin; the sweat glands operate, and the sweat evaporates directly from the skin or from the outer clothing. We can determine by simple calculation what quantities are concerned. About 600 calories are required in the slow ascent of a hill of 500 m. height on a good road. Zuntz estimates that only one-third of this is used for mechanical work and the rest for heat. 400 calories would raise the temperature of the human body (the specific heat of which is somewhat less than that of water) about 6 to 7 degrees centigrade. The evaporation of 690 gr. of sweat would be required in order to prevent this, assuming the latent heat of water at 37 degrees and 580 calories for 1 kg. The human body is also able to increase its radiation of heat prior to evaporation by dilating the cutaneous capillaries and thus increase the evaporization through conduction and radiation. When the outside temperature is low, the body can be relieved of a very large part of the superfluous heat. However, in the summer exhalation can be increased only in the uncovered portions and the amount of sweat, which is lacking in the computation and is generally more than equalized because a part remains in the clothing, and the body in its clothing must excrete much more water in order that a given quantity of water evaporates. Even when the clothing is physiologically more appropriate, a man will excrete at least the specified 690 g. of sweat when he ascends a height of 500 m. in the summer; when clothing is inappropriate, a great deal more.

The importance of our clothing for the regulation of heat and for the evaporation of water from the skin, has, of course, long been recognized through experience. The work of Rubner and his pupils, which ought to be thoroughly studied by every student of medicine, has first shown this with precision. These investigations contain a wealth of proof how, although the clothing is of use in protecting us from cold, during summer this function is reversed; how the cooling off of the body becomes more difficult through the clothing. It is immaterial whether the heat is produced through high temperature without, as in Rubner's experiments, or by the body itself through muscular work. The same experimental human subject emitted through the skin with muscles at rest, but in high temperature during one hour:

	Nude, Grams.	Clothed in Woolen Shirt, Grams.
At 30 degrees centigrade.....	25	85
At 31 degrees centigrade.....	40	100
At 32 degrees centigrade...	55	110
At 33 degrees centigrade....	70	120
At 34 degrees centigrade.....	90	125

In a series of experiments in which the action of the clothes was replaced by greasing the skin, a thermal equivalent, Walpert made the following table, which clearly shows that more sweat was produced than was evaporated, although the air was kept but half saturated with water vapor.

In one hour the skin emitted:

Normal

30 deg. C.; 132 g. of which 13 g. were not evaporated.
35 deg. C.; 243 g. of which 85 g. were not evaporated.
39 deg. C.; 393 g. of which 211 g. were not evaporated.

Greased

30 deg. C.; 165 g. of which 51 were not evaporated.
35 deg. C.; 351 g. of which 191 g. were not evaporated.
39 deg. C.; 457 g. of which 241 g. were not evaporated.

From experience you know how a mountain climber or cyclist who is not clothed appropriately becomes bathed in perspiration. White shirts and smooth lining in our clothes block air passages and water vapor when they have become wet: in this case perspiration is not evaporated and therefore does not achieve its object. The skin is, as it were, in a vapor bath, and the sweat glands must work to the utmost in order to prevent the congestion of heat and a rise of temperature in the body.

Digestion and nutrition have the same effect on the production of heat as muscular work, and the same effect upon the sweat secretion when the temperature without is high. *A full meal is able to increase the secretion of sweat in man by one-half and even more.*

The following table shall serve to give an idea of the water secretion of the body under various conditions:

At rest 14 deg. C., clothed, 42 g. water per hr. (*skin and respiration*).
At rest 25 deg. C., clothed, 85 g. water per hr. (*skin and respiration*).
At rest 37 deg. C., naked, 296 g. water per hr. (*skin respiration*).
At rest, corpulent subject:
At rest 38 deg. C., naked, 345 g. water per hr. (*skin and respiration*).
At rest 20 deg. C., clothed, 108 g. water per hr. (*skin and respiration*).
At work 12 deg. C., clothed, 360 g. water per hr. (*skin and respiration*).
Trades (shoemaker), room temperature 126 g. per hr. (*skin and respiration*).
Trades (bookkeeper), room temperature 53 g. per hr. (*skin and respiration*).

At rest, stomach empty, 27 deg. C. temperature, 31 g. per hr.—skin only.
At rest after albuminous meal, 27 deg. C. temperature, 48 g. per hr.—skin only.
After march of 24.75 km., with 27 kg. baggage, 16 deg. C. 2069 sweat.
After march of 24.75 km., with 31 kg. baggage, 14 deg. C. 2451 sweat.
After march of 24.75 km., with 22 kg. baggage, 26 deg. C. 3447 sweat.
After long march of more than 202 km. in 26 hr. 58 min. at 8 deg. C. 5618 grams sweat. Caspari in Pflügers Arch. 109, p. 473.
Marches of 20-22 km. at 2-5 deg. 175-830 g. skin and respiration.
800-900 m. ascent, 18 deg. below, 93 deg. above, 6 persons active.
789-1692 g. sweat.
800-900 m. ascent, 15 deg. below, 3 deg. above, 6 persons active.
119-759 g. sweat.
1150-1750 m. ascent, 6 persons active, each four marches, 1231-2746 g. sweat.
Zuntz, Löwy, Müller, Caspari in *Höhenklima* Berlin, 1906.

It is clear from this how much water the body secretes as perspiration under given circumstances. The figures here given are surely not the upper limit: in fatiguing climbs, in the glaring sun, 4 to 5 liters are secreted in a few hours. On the other hand, the secretion of water is reduced to very small values during rest and cool weather, and the excretion then probably takes place through the lungs exclusively. The skin is not an organ through which the body rids itself of superfluous water. The copious drinking of water does not increase the secretion of sweat, and even when the body is swamped with liquids, when the kidneys are working to the utmost the serous cavities and intestines are filled with water and the digestive glands are saturated, nevertheless the skin remains dry. The sweat glands, in common with other glands, function only upon specific nervous impulses, which are transmitted to them through sympathetic paths from the thoracic part of the spinal cord. Their physiologic stimulation is known to be a rise in blood temperature, and the interesting observations of Kahn show that they function when the temperature of the blood which passes through the brain is raised. The conducting path from the brain to the sweat glands is therefore by means of nerve fibres. The stimulus, however, exerts itself directly in the brain, exactly as in the case of the breathing centers. This explains why the sweat excretion as a rule takes place over the whole body and not locally.

A suppression of sweat secretion would result in overheating of the body, and further serious consequences. This cannot be directly observed in laboratory experiments on animals, as their physical temperature regulation is different than that of man. The dog does not sweat, but he gives off heat in water evaporation. His breathing becomes extremely rapid and panting, and water evaporates from his open jaws and his lolling tongue—he sweats, as it were, with lungs and jaws. The innervation of the lungs takes place through the N. Vagi. Pawlow, who first successfully performed a double section of the vagi of the dog, noticed that such dogs behaved quite normally; but if they are allowed to run and leap for even a short time, death from overheating will result. The case of a man is known who had a congenital absence of sweat glands. He was perfectly well in cool weather.[1] In heat and during strenuous physical labor, his temperature rose alarmingly. When the temperature rises during fever, there seems to be a lack of function in the sweat production. Occasionally, we can observe conditions in man which result from insufficient cooling, called sun-stroke, a critical rise in temperature, which occurs in the body when the sweat glands do not function because the water reserve of the body is drained.

Where do the sweat glands, as also the digestive glands, obtain their water, and what becomes of water that is drunk? The water that is absorbed passes directly into the blood, whence the glands receive their water. But when more is consumed, the blood cannot be the reservoir as man has but two and a half to three and a half liters of serum. This was mentioned above. The perspiration which he can emit without receiving fluids amounts to more than the total serum; the digestive juices are more than twice as much, and a man may drink in a very short time a quantity of fluid equal to his serum. This experience of daily life was bound to suggest that somewhere in the body water reservoirs must exist. Magnus has actually found them.

Magnus injected diluted and concentrated salt solutions into the veins of dogs. He determined the composition of the blood and the diuresis which resulted during the injection and at intervals afterward. It was found that very considerable quantities of water and salt leave the blood in a few minutes. One dog received an amount equal to almost three times his blood; 2260 cm. very diluted salt solution; when the injection was completed, the blood contained 272 cm. Another dog received 8.75 g. sodium chloride in a concentrated solution, an amount more than twice the salt present in the blood: five min. after the injection, there remained only 1.92 g. in the blood. The water and salt, however, had not passed into the urine; for during the first experiment only 220 cm. of water; in the second 0.5 g. sodium chloride had been discharged with the urine. 1767 cm. of water, with 6.33 g. NaCl could not be found in the blood or urine, they must have passed elsewhere in the body, *i. e.* into the tissues. The experiments of Magnus proved a further fact. As you know, blood contains a certain amount of NaCl and through this and some other salts it has a specific molecular concentration, or osmotic pressure. The vol. of the blood corpuscles and the normal concentration of salt secretions is adjusted to this osmotic pressure, which is maintained by the blood with the utmost regularity. When Magnus injected a concentrated solution of salt, not only did the superfluous salt pass into the tissues, but at the same time water was osmosed into the blood. When a diluted solution of salt was injected, the equalization of the dilution did not take place through water discharge from the blood to the tissues, but also through the entrance into the blood of salt from the tissues. The results of these experiments is therefore: the body has available reservoirs of water and salt into or out of which water and salt can pass and by means of which the concentration of i.e. the osmotic tension of the blood can be kept constant.

These reservoirs are the muscles. According to the experiments of Magnus and Engel, all organs of the body take up some superfluous water when the body is flooded with it. The other organs, however, do this to so small extent (excepting, perhaps, the skin) that the muscles alone figure as physio-

logic reservoirs. There has been no investigation as yet as to whether certain muscles are especially concerned, whether it is the contractile muscular fibre with its fluid contents that thus varies its water contents, or whether the tissues perhaps function as water reservoirs. We only know that the exchange between blood and reservoir takes place in a few minutes and in precisely such a manner as though a simple diffusion membrane were located between the reservoir and the blood. No special regulation between the capillary endothelial cells or other cells could be observed.

The fate of water injected into the circulation in quantities above the vascular capacity has been investigated in this country by Dr. Horatio C. Wood, Jr. (Transactions of the Amer. Therapeutic Society, May 5th, 1905, pg. 28) whose results differ somewhat, though not essentially from those of Magnus. He does not give the complete experimental details of his procedures but the deductions are of importance.

The following were the conclusions which appeared to him to be justified by the evidence he obtained: "(1) The injection of a .7% solution of sodium chloride in any quantity up to four times the total volume of blood has no effect upon the blood-pressure in the normal animal. (2) When the quantity of fluid injected is not more than the total volume of the blood, the greater proportion of the fluid apparently remains in the vessels for a considerable period of time, the pressure in the arteries being kept at the normal height probably by vascular dilatation. (3) When the quantity of injected fluid is greater than the total volume of the circulation, the excess escapes very rapidly from the vessels. (4) This excess does not pass out through the kidney, at least for some time after the injection. (5) A very large amount of the fluid escapes into the gastro-intestinal tract; some apparently leaks through the vessel's walls, especially into the lungs, giving rise to pulmonary œdema. (6) In conditions of low pressure, due either to hemorrhage or to vasomotor paresis, and sometimes in that caused by depressant poisons, the injection of physiological salt solution is capable of increasing the arterial pressure to a point approximately normal. (7) In the great majority of instances this rise is permanent, although in one or two cases, for some reason not determined, it lasted but a few minutes. (8) The rise produced by salt solution is brought about through purely mechanical influence. (9) The subcutaneous injection produces an elevation of blood-pressure in conditions of circulatory depression, but it is much slower in its action than the intravenous infusion. An effect from hypodermoclysis may be expected in about half an hour. (10) No distinct difference in the immediate effects are demonstrable between solutions containing 0.5 or 0.7% of sodium chloride, nor do variations in temperature between 86° to 112° F. apparently affects the results."

The first object of these water and salt reservoirs is to keep the concentration of salt in the blood constant. The concentration of the albumen and the relation between serum and the building up processes which does not concern the osmotic pressure of the blood may vary temporarily; these differences are slowly effaced by the activity of the kidneys. Drinking water, therefore, temporarily dilutes the blood without; however, affecting the salt constituents. The chief part, however, of the water which is beyond momentary need, passes into the water reservoir which in turn enable the organism to deliver the necessary quantities of sweat, digestive excretion, and urinal water. Plehn has shown that man functions precisely as does the dog. (*Deutsches Arch. f. klin. Med.*, 91, 1, 1907.)

As I have said before, the osmotic pressure of the blood serum seems mainly to fill and empty the water reservoirs. However, a series of data seems to admit the possibility of a more complicated control of the exchange of water. It is well to recall that in a case of alcoholic drinks at least, the time for absorption from the digestive tract differs according to the presence or absence of thirst. Let me remind you of the frequent experience of marching or climbing that thirst is better endured when satisfied at long intervals, than when it is quenched frequently. The exchange of water, especially the amount of water discharged through the sweat, seems to be capable of diminution by habit and training. When water leaves the blood, there seems at first to be no reaction, no sensation. It is only when the water reservoirs begin to empty, that the general feeling of thirst is aroused. And it is well known that man drinks without thirst and beyond his thirst. Pure cold water and many other drinks seem to be luxuries to many people. No exact figures can be given on the capacity of the reservoirs. The highest observed by Magnus was 1800 cm. in a dog of 12.8 kg. (28 lbs. 3 oz. 4 drams). The highest delivery was 215 cm. in a dog of 1141 kg. (2515 lbs. 7 oz. 1½ drams). The highest observed retention of salt was 6.3 g., and the loss of salt was much less. Experiments with the secretion of digestive juices, when the latter were removed from the body, show that the chlorine is used sparsely when as little as 3 g. NaCl is removed from a dog of 20 kg. (44 lbs. 1 oz. 3¾ drams). Man can excrete 3—4 liters without difficulty; perhaps considerably more. The upper limit is not known and is probably variable. The water reservoirs are the cause of constant changes in the weight of the body. A man's weight loses several kgs. (7—8 lbs.) through water excretions in strenuous muscular work in the heat, but the albuminous and fatty contents of the body need suffer no change. Such considerable changes, as a rule, are equalized in 24 hours, but these transient fluctuations need be considered in the investigation on metabolism and dietetic treatments. The scales will show considerable increase and decrease which depends solely upon the different amounts in the water reservoirs.

To this I should like to add a few remarks on the influence which the water consumption, a lesser or greater water percentage of our food, is capable of exerting upon functions and phenomena of the body. I do not refer to the excessive diminution of the water which results in thirst, which may be caused by habitual use of very dry or salty food. It is clear that emptying the water reservoirs must disturb the water metabolism and digestion. The blood can not suffer condensation, nor protoplasm the loss of water, hence thirst

brings with it an increased discharge of nitrogen, i. e., collapse, nervous disturbances, death. The question of the effect that physiologic variations in water metabolism exert is much more interesting. Very often the statement is made that drinking or not drinking water has a decided effect upon the albumious or fatty metabolism and deposits; rules for the amount of water figure extensively in many dietetic treatments and popular precepts. It is interesting, therefore, to ascertain the state of our knowledge on the influence which the absorption of water has upon the body.

According to the preceding, the influx of actual addition of the water supply, even in longer periods, cannot be great, consisting essentially in the secretion by the kidneys of *more* or *less* concentrated urine. The regulation of the water reservoirs precludes every other influence, and the resarches of Rubner, Straub, and Heilner, have not revealed a constant or decided influence of the water supply on nitrogen and carbonic acid elimination. Chittendon also found no change in the function of the body in experiments which he continued several months on the effects of diminishing the albumen and food supplies as well as also diminution of water in the food. It is of course, possible that an influence exists which can only be demonstrated under deflnite pathologic conditions; but I should like to refer to the great uncertainty of therapeutic use of water which is not denied by critical clinicians. In some experiments, the workers are dealing not only with increasing or diminishing the water supply, but also with alcohol and other drinks. The suggestive action of every change in the habits of drink must also be considered. Copious fluids are said to flush out and thus aid the organisms. This is doubtful, however, as we know too little about these particular actions of the kidneys and other glands; about osmotic and dialytic exchange between blood and tissues. Copious fluids, on the other hand, are said to deluge the organism, to overload blood and muscles. There are certain popular doctrines which seem to date from antiquity that assert that vigorous muscles contain little water; weak muscles more. In accordance with these maxims, it was recommended that athletes and gymnasts drink less water. The question resolves simply to this, that slaughered meat is valuable if it contains much fat, less valuable if little fat, *i. e.* much water. On the other hand, the water contents of muscles and protoplasm in life have been shown to be very constant. It is doubtful whether the organism can ever be drained other than temporarily; the existence of a "plethora," *i. e.* an increase of blood, has never been proved. The water reservoirs may be drained for a time and the weight of the body much decreased; but the next occasion will probably fill them. Whether they can be surcharged pathologically, no one knows. Medical prescripts on drinking water and on fluid supply are quite dubious. If it is not a question of suggestion or symbolism, physicians will do well to let the thirst of a patient govern his drinking of water, and let other excellent devices of the body regulate the water exchange automatically.

From the aforegoing experiments, it must be clear that deprivation of water in cases of high blood-pressure is not a logical therapy, and in my experience this is borne out by extensive clinical observation. Only when there is evidence of acute nephritis is the exclusion of water a correct plan of treatment; in chronic nephritis water is not only permissible, but is benencial.

Water metabolism in relation to blood volume and absorption of water by alimentary tract to make up deficiencies in the blood volume.—This subject has recently become one of great importance, because of the treatment of exhaustive hemorrhages due to wounds received in battle. It received the attention of P. Rous and G. W. Wilson, (*J. A. M. A.*, 1918, vol. 70, p. 219) who found in animals that when the total hemoglobin was reduced to one-fourth of the original normal amount, that the animal could still recover if the blood volume was maintained. But when the amount of the total hemoglobin fell to one-fifth of the normal, the animal did not survive even though the blood volume was kept normal.

The subject has been carefully studied upon wounded soldiers by Oswald H. Robertson and Arlie V. Bock, both Captains in the Medical Corps of the U. S. A. and published in the *Jour. of Experimental Medicine*, vol. 29, p. 2, Feb. 1, 1919.

The hemoglobin is the oxygen carrier of the blood. If it is reduced, let us say to one-fourth its normal amount, the processes of the organism oxidation might still be carried on fairly satisfactorily if this reduced amount of hemoglobin could be made to pass through the lungs four times as frequently as it did in the normal animal. In an animal (dog 5 kg. in weight) with a normal blood volume, and only 25% of its normal hemoglobin, this quantity of hemoglobin would pass through the pulmonary alveoli once in a minute; but this is the time required for a normal blood volume with a normal amount of hemoglobin. If now, the same amount of oxidation has to be done with only one-fourth the amount of hemoglobin, this quantity of hemoglobin would have to be forced through the lungs four times in one minute. These are not actual figures from physiology, but just examples to facilitate the conception of the problem. If a hemorrhage, however, has reduced the hemoglobin to one-fourth its original volume, and the amount of blood plasma has correspondingly diminished, it would not be wise to restore the water of the blood to the normal without restoring the hemoglobin to the normal, also. Assuming that we could restore the blood volume to the normal, and not the hemoglobin, the circulation time would still be one minute and in that time the fourth of the normal hemoglobin could not accomplish sufficient of oxidation because it would pass through the lungs only once instead of four times in a minute.

Robertson and Bock have shown that the extent to which the blood becomes diluted through restoration to its volume after hemorrhage, depends within certain limits, on the total amount of hemoglobin remaining. They observed in patients, with a very low hemoglobin per cent., that the blood volume did not show a marked increase until the amount of hemoglobin rose, no matter how much fluid they were given.

There appear to be two forces at work; one

favoring dilution, and the other inhibiting or checking dilution of the blood. The one which tends to restore the blood bulk, so that the circulation has a sufficient volume to work with effectively, and the other, a mechanism which apparently tends to prevent the blood from being diluted too much, with a consequent lowering of the hemoglobin per cent. Until a very low per cent. of hemoglobin is reached by bleeding an animal or traumatic hemorrhage in man, the former force is stronger, and the blood dilutes to a volume needed for good blood pressure.

There seems to be a point at about 20 per cent. hemoglobin where the force that inhibits dilution becomes the more effective and the blood does not dilute any further, even though the volume may be so small as to be barely compatible with life.

Robertson and Bock give illustrative cases of these processes.

"Case 4 (Text-fig. 4) showed a condition of profound anemiahemoglobin 20 per cent. A fairly large fluid intake was maintained, yet the blood showed no tendency to dilute, even though the volume was less than 68 per cent. of the normal. Case 5 (Text-fig. 5) shows a first hemoglobin reading of 26.5 per cent. and 30 per cent. from vein and ear respectively. At this time the blood volume (estimated) was 2,605 cc., or 56 per cent. of normal. This volume was evidently too small for the circulatory needs, and dilution was permitted to occur until the hemoglobin remained practically stationary, the volume having increased meanwhile sufficiently to bring the blood pressure up to normal."

In order to illustrate the value of a large intake of fluid by the mouth and rectum, indeed its superior value to transfusion for the purpose of restoring blood volume after hemorrhage, I will quote the operations of Robertson and Bock in their summary (l. c. page 166).

"Blood volume tests made on a number of soldiers recovering from hemorrhage have shown that in many instances dilution of the blood occurs very slowly. The principal reasons for this seem to be (*a*) an initial lack of reserve fluid of the tissues, and (*b*) the absence of any subsequent attempt by the body to make up this fluid deficiency.

"By putting such patients on a large fluid intake by mouth and rectum it has been found that their blood volume can be promptly and greatly increased. Hemorrhage cases transfused, yet still showing a low blood volume, were first treated in this way. Then the effect of forced fluids without transfusion was tried. Immediately after a hemorrhage, or as soon as the patient came under observation, he was given large quantities of water by mouth, and salt solution by rectum. Under such treatment the blood pressure soon began to show a progressive rise, the volume increased, and the red cells became more evenly redistributed, as shown by the relative hemoglobin percentages of the capillary and venous blood. These changes were often well marked after only 2 or 3 hours of the treatment.

"More than this, forcing fluids in cases where the amount of bleeding is difficult to estimate on account of the presence of a high hemoglobin percentage is of distinct value, since the dilution of the blood which results, serves to show the extent of the hemorrhage through the drop in hemoglobin that it entails.

"In attempting to determine the condition of the patient after hemorrhage with a view to deciding the most suitable form of treatment, it is of much importance to learn the total blood loss—which is often not even indicated by the hemoglobin concentration of the remaining blood. With a total hemoglobin reduced to 25 per cent. or under transfusion is needful. New blood is necessary, not only to supply more oxygen-carrying cells, but also because it actually enables the circulation to increase its volume. For, as has been pointed out in Paper 1, by Robertson & Bock (*l. c.*), the hemoglobin percentage must be above a certain point if a rapid restoration of the blood volume by means of the organism's own activities is to come about. With the total hemoglobin about 25 per cent. the chief need is for increased blood volume, and if the patient's condition demands an immediate and large addition of circulating fluid, gum acacia solution should be given. If the condition is not so urgent, forced fluids by the alimentary tract are indicated.

"The blood volume can be considerably reduced and yet a normal blood pressure maintained. It is pointed out that the vasomotor mechanism which has adapted itself to the diminished blood bulk may in any individual case be very near the margin of its compensatory power. Increased strain in such instances may cause a failure of this mechanism with a resulting fall in blood pressure.

"The beneficial results of forced fluids after secondary hemorrhage suggest the value of the early use of fluids by the alimentary tract in cases of primary hemorrhage."

Schema for Clinical Investigation of Human water Metabolism. Determination of normal weight and specific gravity of the body.

S. G. of a body is the ratio of the mass of that body to the mass of an equal volume of water. The human body must first be weighed in air and then, when it is submerged in water, the difference between these two gives the weight of a mass of water whose volume is equal to that of the solid weighed. To determine S. G. of human body it is only necessary to divide the weight as observed in air by the loss of weight when submerged in water.

Deductions and Conclusions.—1. Necessity of determining the General Water Metabolism in all complete diagnostic surveys of the body.

2. Degree of sweat elimination at given temperature and in given time and the measured water intake. Analysis of the sweat.

3. Amount of blood in body and the amount of electrolytes it contains. Blood specific gravity.

4. Degree of water elimination through the kidney. Analysis of urine and its chemical constituents.

5. Rate of absorption of water from gastrointestinal tract.

6. Elimination of water, etc., through lungs. Respirometer studies at given temperature, measured blood pressure, and known water intake and output.

7. General H_2O intake and output at given age and temperature.

8. The blood pressure and heart condition by auscultation, percussion, radiograms and electrocardiograms.

9. The specific gravity of the entire body and the specific gravity and osmotic pressure of all obtainable body fluids.

10. The study of sweating and of the secretion of urine. Diarrheas—Profuse spitting or expectoration after nerve disturbances.

Diminished quantity of any of these secretions after nerve disturbances. Relation of the endocrine systems to these secretions.

SPLENOMEGALIC HEMOLYTIC JAUNDICE:

CASE REPORT FOR CONGENITAL TYPE.

By CHARLES L. McVEY, M.D.,

OAKLAND, CAL.

VISITING PHYSICIAN, UNIVERSITY INFIRMARY, BERKELEY.

Two types of splenomegaly with hemolytic jaundice are recognized: (1) the congenital or familial or Chauffard-Minkowski, and (2) the acquired or Hayem-Widal. Chauffard has said that in the congenital or familial cases the subjects "are more icteric than sick," and frequently come for treatment for other things, considering the jaundice as a family idiosyncrasy not interfering with perfect health. This type is compatible with long life, and in one case reported, the patient reached the age of 70 years.

In the Chauffard-Minkowski type there is present a chronic jaundice which may not be apparent except upon close inspection. The jaundice varies in its intensity from time to time, and is often found increased following undue fatigue, biliary colic, or exposure to cold. Bettman's patient even experienced attacks of hemoglobinuria brought on by exposure to cold, and Wiesom, in cases of children, found that a cold bath brought about a daffodil color in the skin. Symptoms of cholemia such as itching, multiple hemorrhages, bradycardia, etc., are never present, and it seems to have been definitely proven that the jaundice is not due to biliary obstruction, although gallstones are frequently found at autopsy or operation. Note the 17 cases reported from the Mayo Clinic in 1917 (4 of the acquired type). Twelve splenectomies were performed. In 58 per cent of these gallstones were present.

The cause of the jaundice has not been definitely determined. Is it due to the constant destruction of circulating erythrocytes with the consequent liberation of hemoglobin, or is it due to the damming up of hemoglobin in the liver itself? Whipple recently has shown that bilirubin can be formed by the action of the endothelium of blood vessels entirely isolated from the hepatic circulation.

Rarely all the signs and symptoms of the disease may be present except the jaundice, as in the family described by Chauffard. In this case an eighteen year old son evidenced all signs except jaundice. The mother was a typical hemolytic icteric.

Attacks of gallstone colic or perisplenitis are common, or, as in the case here reported, several "bilious" attacks during a year may occur. In these attacks diarrhea, headache, and slight fever may be present. The urine is generally highly colored, due to the presence of urochrome. Urobilin or urobilinogen are present, and very rarely bile. The stools are of normal color. Both urobilin and bile are always present, and it has been shown by Moller that the total urobilin excretion in urine and feces is greatly increased.

Krumbhaar studied 158 cases in which blood counts were available, and found 55 belonging to the acquired type, 103 to the congenital or familial type. Of these 103 only 23 failed to give a positive family history, whereas of the 80 familial cases 35 developed after birth. The average blood count of the 103 congenital and familial types was 3,340,000 (1,800,000 to 5,700,000) while the average for the acquired type was 2,032,000 (510,000 to 4,500,000). A secondary anemia is nearly always present. A severe anemia in hemolytic icterus may very closely resemble a pernicious anemia. Widal and Weissenbach have reported a case of this type. However, in the usual Biermer type of pernicious anemia the resistance of the red cell is increased, icterus is absent, and the spleen shows but slight enlargement. In chronic splenomegalic hemolytic jaundice the red cells show a predominating microcytosis, and only slight poikilocytosis and anisocytosis. Chauffard tested the degree of the fragility of the red cell when subjected to varying strengths of hypotonic salt solution, a test first suggested by Ribierre in 1903.

Various agents, such as snake venom, bacterial hemolysins, saponin, and specific hemolytic immune sera, have been employed experimentally in the study of hemolysins. Hypotonic salt solution is most commonly used. In general, an increase or decrease of resistance to hypotonic salt solution is an index as to the increase or decrease of resistance to any of the other agents. The use of hypotonic salt solution is entirely satisfactory, then, as a test for erythrocytic fragility.

Normally, when erythrocytes are subjected to hypotonic salt solution hemolysis begins at .45 and is complete at .35. In chronic splenomegalic hemolytic jaundice hemolysis begins at some higher point and not infrequently at .6 or .7. It has been shown that the fragility test is much more sensitive when washed red blood cells are employed.

The cause of the fragility is unknown. Widal, Abrami, and Brulé produced experimentally in animals a lessened resistance of the red cell by intraperitoneal injection of toluylendiamin. The degree of resistance could be increased or decreased by a concomitant increase or decrease in the dosage.

In this disease we may surmise a circulating toxin producing a destruction of the erythrocytes together with bone-marrow stimulation and the liberation of immature, less resistant erythrocytes. However, no such toxin has ever been isolated. It is remarkable that the congenital and familial cases show a greater degree of compensation than the acquired. The anemia is less severe and the patients are less toxic, as if a gradually developing resistance to a circulating toxin had been established.

Does the hemolysis occur in the spleen or in the

general circulation? Minkowski, Chauffard, and Vaquez believe that the abnormally fragile corpuscles are destroyed in the pulp of the spleen. Widal and others believe that the destruction occurs in the general circulation, the débris accu-

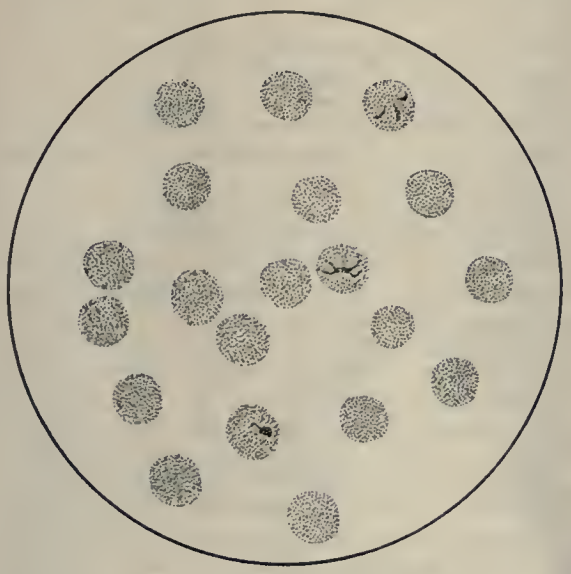

FIG. 1.—Normal, granulated.

mulating in the spleen. The occurrence of siderosis in the kidneys favors the circulatory origin.

Normally, less than one per cent. of erythrocytes show reticulation, whereas in chronic splenomegalic hemolytic jaundice they are present in amounts up to 40 per cent. A detailed study of this phenomenon was made by Vaughan in 1903 although it was originally described by Pappenheim in lesser detail. It was shown that the blood of the newborn shows an average of four per cent. reticulation; in pernicious anemia with active regeneration, 18 per cent. In splenomegaly with hemolytic jaundice the percentage ranges from 10 to 40. The degeneration is entirely independent of the basophilic granulation of Grawitz demonstrated in fixed blood smears stained with ordinary blood stains, or the Schüffner's granules appearing in the malaria-laden erythrocyte stained by the Romanowsky method.

The appearance of the reticulation is thus excellently described by Thayer and Morris:

"Many of the red blood cells which are of a slightly grayish color, and barely visible, having lost their refractiveness with their hemoglobin, show a fine granulation of a bright red color. These dots, generally arranged about the periphery, are sometimes scattered throughout the cells in the form of a definite granulation. The granular corpuscles are usually somewhat larger than their neighbors. The distribution of the granules is irregular. Sometimes scattered, they are usually collected in groups of two or three. Sometimes they are arranged in the form of a wreath or crown at the periphery of the corpuscle. They are generally distributed in such a manner as to suggest filaments wound around within the cell, and showing varicosities. They are unequal in size and of irregular form. Not infrequently this granular network is gathered together toward the periphery or near the center of the cell in such a manner as to suggest grossly a nucleus. Sabrazés has called these corpuscles reticulo-filamentous. The apparent reticulum is very adherent to the red blood corpuscle. If a dried and stained specimen be washed with pure water, the corpuscles lose their blue color, while the granular filamentous appearance remains. Indeed, in some cases, the reticulum may be found outside the corpuscle, lying between other well preserved elements. According to Fiessinger and Chauffard, the average diameter of the reticulated cell is 8.1 micra as compared with an average diameter of 6.3 for the non-reticulated cell."

The presence of reticulated erythrocytes in excessive amounts generally signifies active blood regeneration, and this regeneration is manifested in the Chauffard-Minkowski type in this manner rather than by the presence of a great number of nucleated erythrocytes as occurs especially in pernicious anemia. Again, the presence of nucleated erythrocytes in the circulation does not always mean excessive blood regeneration, since it occurs in certain rare conditions such as tumors of the bone-marrow. Reticulation is easily demonstrated in the following manner:

Method of Rosin and Bebergeil.—A one per cent. alcoholic (95 per cent.) solution of brilliant cresyl blue is used. A drop of this mixture is placed on a slide and is then converted into a thin smear by drawing the ground edge of another slide across the glass surface. The slide should be slightly warmed to make evaporation of the alcohol rapid. Evaporation of the alcohol leaves a thin film of dye on the slide. A small drop of blood is placed on a cover slip and the cover is then inverted and placed on the slide so that the blood lies between the cover and the slide. A thin film of blood is thus obtained. The blood plasma dissolves the dye which is then taken up by the red and white cells. The edges of the cover slip

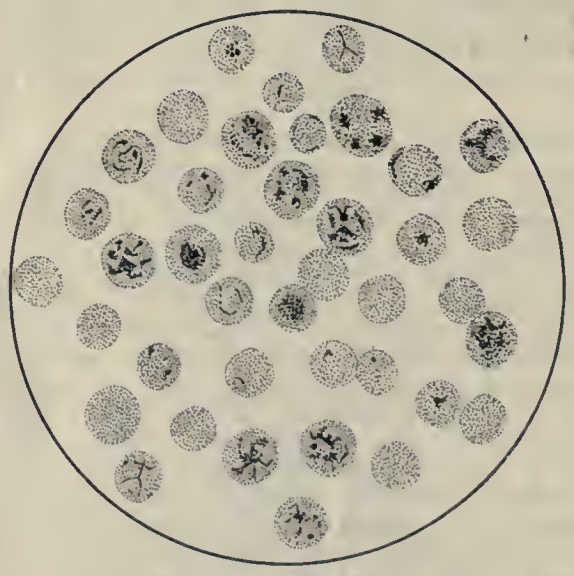

FIG. 2.—Red cells of various sizes showing more or less reticulation.

are sealed to the slide with vaseline, or preferably heated paraffin. If the slide is correctly made it should show a single layer of cells, none of which are crenated.

Solutions of less than 1 per cent. of brilliant

cresyl blue will show reticulation in the red blood cells but not as well as the saturated solution (1 per cent.) In normal blood the percentage of reticulated cells is roughly 0.1-0.5 per cent. It is probably nearer 0.1 than 0.5 per cent. In normal blood, several fields will require examination before any reticulated cells are discovered.

Neither Fig. 1 nor Fig. 2 shows cells from a single field, but an attempt has been made to show the general types of reticulation. Where the reticulation is very heavy, the plasma also may be slightly tinged with the dye. In Fig. 2 one-third of the red cells show some reticulation. The red blood cells of Fig. 2 show considerable variation in size, the largest ones in general being the most heavily reticulated.

Polychromatophilic degeneration is generally present. An occasional megaloblast or normoblast may be seen in the dried stained specimen. Nothing unusual is found in the white and differential count. The blood platelets are present in normal amount. Coagulation time is normal. The

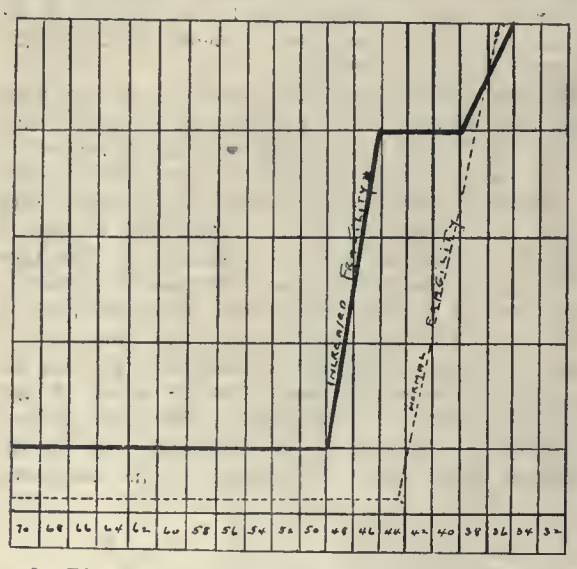

FIG. 3.—Diagram of fragility with the use of hypotonic salt solution.

blood serum is hypertonic, resulting from the exosmosis of inorganic salts from the fragile erythrocyte (Troisier). The serum is of a clear, yellowish color. The bilirubin test is positive. Urobilin is generally undemonstrable.

The acquired or Hayem-Widal type does not present a definite disease picture to the same extent as does the congenital or familial type, but rather an interesting syndrome. Soon after the observations of Chauffard, a similar syndrome was reported by many observers as occurring in adult life. It was seen to follow ischiorectal abscess, severe nervous shock, gastroenteritis, hemorrhage following miscarriage, etc. At other times, apparently the disease began independently, and without exciting cause. Transient jaundice, increased fragility of the erythrocyte, secondary anemia with reticulation of the erythrocytes, may occur in cancer of the stomach, cirrhosis of the liver, malaria, repeated hemorrhages in cancer of the bladder, streptococcus infection, uncinariasis, syphilis, pulmonary tuberculosis, and jaundice of the new-born.

Definite crises occur in the acquired type of the disease. Attacks of abdominal pain are followed by a great increase in the intensity of the jaundice, and this is followed by a severe secondary anemia. These attacks have been called by the French "crises of deglobulization."

Krumbhaar has noted the following conditions in which enlargement of the spleen may occur. In one group may be classified:

(1) Various hemolytic anemias of specific origin (*Dibothriocephalus latus* and uncinariasis).

(2) Lesions of the spleen associated with thrombosis of the portal vein or artery.

(3) Splenic types of cirrhosis of the liver.

(4) Leukemia, pseudoleukemia, and changes secondary to obstruction or infection, as in heart disease, typhoid fever, kala azar, syphilis, etc.

In another group:

(1) Gaucher's disease.

(2) Banti's disease.

(3) Von Jaksch's disease.

(4) Chronic splenomegalic hemolytic jaundice.

(5) Pernicious anemia.

In the acquired type the onset is sudden, and the patients are always distinctly ill. They present the picture of a grave anemia which shows some resemblance to pernicious anemia. The erythrocytes are fragile, but to a lesser degree than in the congenital or familial type. It is very essential, then, to demonstrate the fragility with washed corpuscles. The phenomenon of autoagglutination is present in the acquired type, but not in the congenital or familial type.

Five theories have been offered as to cause:

(1) Congenital communication between the bile passages and lymphatics (autopsies have disproved this).

(2) Hayem believed the disease was due to syphilis. The absence of a positive Wassermann in the majority of cases would seem to disprove this theory.

(3) Icterus and splenic enlargement due to chronic cholangitis. This is difficult to imagine, because the condition dates from birth and continues throughout life, yet leaves no indication at post mortem.

(4) Minkowski's theory of congenital perverted function of the liver cells by virtue of which bile is secreted in part to lymphatics instead of into the bile capillaries. This might account for the jaundice but not for the enlargement of the spleen.

(5) The best theory was offered when Chauffard discovered the increased fragility of the red cell. The cause of the fragility remains to be discovered. (1) Is it a congenital defect of metabolism leading to production of toxic substances deleterious to the red cells, or is it (2) a congenital defect in the blood-forming organs?

Pathology.—Hemosiderin may be found in the liver cells, and also in the kidneys, but to a lesser extent. The splenic enlargement is due both to passive congestion and to siderosis. Fibrosis is not present.

Treatment.—Splenectomy brings about more gratifying results in this disease than in any other disease in which great enlargement of the spleen is a prominent feature.

Elliott and Kanavel collected 48 cases up to the year 1915. Splenectomy was performed upon all of these with only two deaths. The blood was restored to normal to a great degree. It was found that the fragility of the erythrocyte was lessened to a great degree, but was never entirely restored to the normal.

In Sir Spencer Wells' case increased fragility was noted 27 years after operation; in Roth's case, 3½ years following operation.

During the first few days following splenectomy the jaundice increases, but in nearly all cases is entirely absent at the end of two weeks. The "crises of deglobulization," with the accompanying malaise, headache, and fever, cease entirely.

W. J. Mayo, writing of splenectomy, says that the mortality of splenectomy depends more on the type of cases accepted for operation than on the technical difficulties of the operation itself. If the patient is in good general condition, a small, movable spleen can be removed with a death rate so low as to be almost accidental. If the spleen is enlarged, but has considerable latitude of motion, splenectomy may be performed with almost no mortality beyond the possible accidents of a serious operation; but if the spleen is large and adherent, and the patient is suffering from a high grade of anemia with myocardial and renal changes, marked by edema of the lower extremities, or is suffering from ascites, jaundice, high temperature, etc., etc., mortality will necessarily be high. Even under these conditions, surprisingly few patients die directly as the result of the operation.

Report of Case.—Miss H. C., age, 18 years; female; single, student; nativity, California.

Family History.—Father alive and well at 52 years; mother alive and well at 42 years; one brother alive and well at 16 years; one brother alive and well at 14 years. There is no history of splenomegalic hemolytic jaundice in the family.

Previous Diseases.—Measles at 4 years; mumps at 6 years; whooping cough at 6 years; tonsillitis, repeated attacks between 8 and 9 years of age; epistaxis repeated during the year 1917; "biliousness," once or twice yearly experienced "bilious" attacks. These were ushered in by nausea and vomiting, but abdominal pain was never at any time present. "Influenza" in October, 1918, complicated by a bronchopneumonia of moderate severity. No sequelæ. Menstruation began at 13 years; always regular. Injuries: at the age of 10 years fell from a "swing" striking upon the head. Was unconscious for a period of one-half hour. Habits: exemplary.

Present Complaint.—Lassitude. This complaint had never been serious enough to call for treatment. The disease was discovered during the course of a routine physical examination given all entrants at the University of California.

Physical Examination.—General appearance: Medium build. Skin and mucous membranes pale. Conjunctivæ icteric. Psychic: normal. Heart: There is a faint systolic (hemic) murmur at the mitral orifice, not transmitted to the axilla. Lungs: normal. Spleen: Greatly enlarged, and extending three fingers-breadth below the umbilicus. No other glandular enlargement. Liver: cannot be palpated. Reflexes: normal. Sensory: normal. Urine: negative. Blood: Hemoglobin, 55 per cent.; Reds, 2,400,000; Whites, 8,900; polys., 70; small monos., 26; large monos., 4; eos., 0; Platelets, 300,000. Malaria: negative. Poikilocytosis and anisocytosis: moderate. Increased fragility of red cells. Reticulated red cells: 40 per cent. Stool: no ova or parasites; urobilin present. Occult blood: negative. Blood serum: Wassermann negative.

BIBLIOGRAPHY.

An excellent bibliography covering the literature of this subject up to 1911 may be found in an article by W. S. Thayer and R. S. Morris: "Two cases of congenital hemolytic jaundice with splenomegaly; Observations on hemolytic jaundice." Bull. Johns Hopkins Hosp., 1911. V. 22:85.

THOMSON BUILDING.

THE PROPHYLAXIS AND TREATMENT OF GALLSTONE DISEASE.

BY SAMUEL WEISS, M.D.,

NEW YORK.

ATTENDING GASTROENTEROLOGIST JEWISH MEMORIAL HOSPITAL, LECTURER ON MEDICINE AND DIETETICS, NURSES' TRAINING SCHOOL, FELLOW AMERICAN CONGRESS ON INTERNAL MEDICINE.

SURGERY has a distinct place in the treatment of gallstones, but the treatment of gallstone disease may with truth be said to be entirely medical. Upon consideration of post-mortem records it is seen that from 6 to 10 per cent. of all cadavers show the presence of biliary calculi and when it is shown that not more than 1 person in 20 of those who harbor gallstones becomes aware of their presence as evidenced by symptoms, in many instances insufficient to require operation, it is readily demonstrable that the field of surgery is decidedly limited, although of great importance in selected cases. Keeping these facts in mind, and remembering the distinction between gallstone disease and gallstones, more will be expected of the internist and fewer disappointments will be attributed to the failure of surgery.

The general medical treatment of gallstones, and the various manifestations of the same may be considered under the following heads: The prevention of stagnation of bile; the prevention of the occurrence of catarrhal inflammation of the gall-bladder and bile ducts; the removal of catarrhal inflammation when it has appeared; the attempts to remove calculi from the gall-bladder and the ducts; diet, spa treatment, vaccines, and local therapy.

Stagnation favors infection, cholecystitis, and hence the production of gallstones, or if these are already present, an immediate attack of colic. It is therefore important that stagnation should be prevented as far as possible and for this object the following methods may be adopted:

1. Exercise leads to increased movements of the diaphragm and liver and so to an increased flow of bile into the duodenum. Horseback riding is perhaps the best, but bicycling, climbing, rowing, and tennis are excellent. Deep respirations should be practised, so as to induce vigorous movements of the diaphragm and the liver. After pregnancy the lax condition of the abdominal wall which favors enteroptosis, hepatoptosis, and stagnation of bile may be met by massage of the abdominal muscles, care being taken not to bear directly on the gall-bladder, since cholecystitis may thus be set up.

2. Attention should be paid to the dress; the corset, tight waist bands, and heavy skirts should be avoided.

3. Meals at short intervals are more effective than large meals at long intervals. In addition some supper should be eaten before going to bed. When food passes into the duodenum, bile is driven out of the gall-bladder into the duodenum.

4. Vichy, Carlsbad, or hot water containing sulphate or phosphate of soda may have a good effect and act as a cholagogue. In order to get the maximum effect from the water, it should be taken before meals when the stomach is empty. The water should not be taken in excessive quantities or too hot, otherwise dilatation of the stomach may occur.

5. Although a number of drugs have been credited with the power of increasing the secretion of bile, it is now generally agreed that salycilate of soda and bile salts are the only drugs. Salicylate of soda also acts as an intestinal antiseptic tending to diminish intestinal catarrh.

In the prevention of catarrhal inflammation it should be remembered that indigestion and gastritis, by leading to gastroduodenal catarrh, might set up catarrhal inflammation of the bile ducts, which must be treated by careful dieting, drugs, and the prevention of constipation. For this purpose my usual prescription is an old formula of the late Dr. William Hanna Thomson, consisting of phosphate of soda, 2 oz., salicylate of soda, 3 drams, and benzoate of lithia, 1 dram, divided into twelve powders, one powder to be taken in a glass of hot water and sipped slowly on rising every morning. A half tumbler of natural Carlsbad water with a little hot water before breakfast or one or two drams of Carlsbad salts dissolved in hot water are useful. The Carlsbad salts are better borne by the stomach if a little infusion of quassia or chinchona is added to the draught. After taking the salts, the patient should walk about, or better, practise systematic exercises with deep inspiratory movements to favor the descent of the diaphragm, and should not have any food until an hour after the draught has been taken. Worry and anxiety are frequent causes of dyspepsia, and in this way may be instrumental in favoring infection of the ducts and gall-bladder. Focal infections such as pyorrhea, sinusitis or a chronic appendix may be the starting point of a cholecystitis, and this way predispose to the formation of calculi.

It is important to remove catarrhal inflammation of the biliary and intestinal tracts, because calculi are formed as a result of catarrhal cholecystitis and are likely to keep up the irritation and predispose to attacks. The methods already referred to by which the flow of bile is increased and the bile passages washed down are of use in removing catarrhal inflammation of the gall-bladder and bile ducts. The abdomen should be kept warm to avoid chills, and in cases where there is tenderness over the gall-bladder, poultices, hot packs or fomentations, or heat by means of the thermophore may be applied over the right hypochondrium.

The treatment of gallstones consists in treatment for relief of the painful acute attack and treatment of the patient between attcks. In acute biliary colic the pain is so agonizing that it often needs the hypodermatic administration of morphine for its relief, or the patient may be kept lightly under the influence of chloroform inhalations. I personally have discarded morphine as a dangerous and habit forming drug, and in its stead employ a tablet of 1/150 grain of atropine dissolved under the tongue, or a suppository of extract of belladonna, 1 grain. Amyl valerate in 15 grain capsules repeated every 4 or 5 hours may prove effective and should, if possible, always be given in preference to any opium derivative. Antipyrin given early in the paroxysm may prove useful, and hot applications, unless contraindicated by cholecystitis, may be tried over the hepatic region. In less severe cases, the patient may be put in a hot bath and given tincture of belladonna, eight minims in about a teaspoonful of spirit of chloroform. The vomiting accompanying the attack hardly requires any special treatment. Bismuth, soda, or dilute hydrocyanic acid may be given. I employ hot water containing bicarbonate of soda, which relieves purposeless retching by giving the stomach something to bring up. If retching persists, and the patient is in a state of collapse, iced champagne may be given. Within the past year a new remedy made its appearance which has given me quite some satisfaction in relieving, and sometimes preventing, attacks of biliary colic. This drug is benzyl benzoate, which has been extensively described by D. I. Macht of Baltimore.

Treatment between Attacks.—According to the surgeon, an operation will be the best way to relieve or cure the patient. The surgical treatment, as previously asserted, should be confined to those instances of the disease in which mechanical removal of the foreign body is necessary, the procedure in each case being adapted to the patient in hand. It is difficult to see how operation can do more than relieve the condition present at the time of the undertaking, for even removal of the gall-bladder can hardly prevent the further formation of calculi in the bile ducts. It is within the medical man's power to advise a change in the patient's mode of life which will tend to prevent or diminish the liability to catarrhal inflammation of the gall-bladder and bile ducts. The points to be borne in mind are to prevent stagnation of bile in the biliary tract, or to obviate or remove any inflammatory condition of the mucous membrane of the duodenum, biliary papilla, bile ducts, etc. Gentle exercise, in the fresh air if possible, to favor the passage of bile into the intestines is advisable. When this is not practicable, breathing exercises to increase the movements of the diaphragm and liver should be instituted. Stooping over desks and working in cramped positions must be corrected, while the use of tight corsets, belts, etc., should be discontinued. The patient should be warmly clad to avoid chills.

In attempts to remove calculi, numerous drugs have been tried. A very famous ancient remedy was Durande's ether and turpentine mixture, fifteen drops of the former and ten of the latter in a capsule. I have found it to be ineffectual and nauseating. Olive oil has been widely used to relieve the symptoms or in attempts to remove calculi, but there is no evidence that olive oil given by mouth much less by rectum, can act on calculi in the gall-bladder. In fact, a well known fallacy about some of the good effects ascribed to olive oil is that the

oil itself may be digested and altered so as to imitate softened calculi when passed by the bowel. Some of the good effects of oil may be due to its soothing and antispasmodic action on the intestine. Since the bile acids dissolve cholesterin, any increase in the secretion of the bile, such as is induced by salicylates or by the administration of bile by mouth, may be regarded as a means of dissolving calculi. Since protein food increases the percentage of bile acids in the bile, meat has been regarded as an important element in the diet of patients suffering from gallstones. The use of bile acids and their salts is more scientific than the administration of bile itself because they are the physiologically active principle of this substance, and any danger from the introduction of poisonous bodies from the bile, which really is an excretion, is thus avoided.

Acid sodium oleate, like salicylic acid, is excreted by the epithelium of the bile ducts and so assists in disinfection. If the acid sodium oleate is carefully prepared and is combined in a pill with salicylic acid obtained from natural sources, also phenophthalein, and menthol, which is a carminative, acts as an intestinal antiseptic, increases peristalsis, and allays nausea, it will be an efficient agent in combatting gallstone disease. The dose of these pills is 4 to eight pills daily with a full glass of hot water. Following this medication the elimination of gallstones of the hepatic variety is generally rapid. In order that the process may be painless, amyl valerate, 15 minims in capsules, may be given two hours before breakfast and after supper. I have found that a combination of sodium phosphate, sodium bicarbonate, and sodium sulphate, equal parts of each, given in hot water before meals, has given satisfactory results and caused expulsion of sand and stones. In other cases, I have employed a capsule of sodium succinate, sodium glycocholate, sodium benzoate, and phenolphthalein. Still in others I have prescribed eunatrol (sodium oleate) both in pill and emulsion, with marked success. Oleic acid, eight minims in capsule morning and evening, has given satisfactory results.

Where there is much bloating of the lower intestines, enemas containing a half to one teaspoonful of turpentine and not over a quart of water in volume can be given one to three times daily. The patient on arising should drink slowly 10 to 12 ounces of hot water containing a powder of either sodium phosphate, sodium sulphate, and sodium bicarbonate, or of other salts which will regulate the stools and overcome constipation. For gastric distress or flatulency a prescription containing some carminative and antifermentative may be given. Other drugs should be prescribed according to indications.

The secret of successful treatment is to gain the patient's confidence and cooperation, and the persistency of treatment, as I have found that each patient is a law unto himself and that the same drug will not act the same way in a similar case in another patient.

As to the kind of food most suitable for patients with gallstones, considerable divergence of opinion has been expressed, but a variety of flesh food, broiled or boiled, may be employed. All fats should be interdicted so far as possible. Alcoholic drinks must be forbidden. Sugar in any form must be limited. Frequent small meals are desirable, because in this way the duodenal papilla is made to open reflexly and the bile allowed to pass into the intestines. It seems that increased cholesterol in the circulation plays a part in gallstone formation and therefore under this head comes the interdiction of yolk of eggs, peas, fatty meats, and all fried foods. I have used such methods and I can point to innumerable persons who undoubtedly have been gallstone sufferers and who are free from symptoms.

It has become apparent that the important feature of the treatment of gallstone disease is the regulation of catarrhal conditions and inflammations in the portal system and dependent organs as above outlined. In some cases it is advisable to suggest spa treatment, and success is based upon the fact that at the resort the patient's habits of life are regulated, the diet is controlled, and the use of the salines diminishes congestion and inflammation in the portal area. Of these Neuenhar, Kissingen, Vichy, and Carlsbad in Europe have been the favorite health resorts of many. Since the war prevented these migrations Saratoga Springs has become a popular health resort. During the summer I refer there as many as forty to fifty patients who are to undergo the cure. It is important that these patients place themselves under a physician's care and receive proper directions as to diet, baths, and drinking the water, as often more harm than good may result from improper treatment.

Vaccines constitute a specific form of therapy if the causative organisms have been isolated. We can readily accomplish this by means of a duodenal tube, and in this way the bile can be studied directly as is gastric secretion, and the various forms of chemical analysis can be applied to the material removed. We can examine the bile for cholesterol, bile-pigments, etc.; the microscopic examination will show the presence of mucus, pus, and blood; the bacteriologic examination will determine the presence of pathogenic organisms. These procedures depend on an accurate method for obtaining the bile. It will be necessary to examine the patient on a fasting stomach; the mouth is rinsed with an antiseptic solution and a sterile duodenal tube is passed into the stomach. The aspirated bile is studied as above described and then cultured and the pathogenic organism or organisms are isolated and an autogenous vaccine prepared. In several of my cases a pure strain of colon bacillus was isolated and in others staphylococci of various strains were recovered.

In some patients we may find foci of infection elsewhere and therefore make cultures from the nose, throat, teeth, or urine. When a definite strain is located in the gall-bladder we make a polyvalent vaccine consisting not merely of the organism isolated from the bile but of the same organism found elsewhere. A difference of virulence undoubtedly exists and this method contributes to the likelihood of an effective antigen.

Autogenous vaccines are preferable to stock vaccines, but the presence of organisms elsewhere which are persistent and suspicious in the mind of the clinician, should be borne in mind. I believe that the good results obtained have always been due to this precaution.

Small doses, frequently repeated, are given, and

increased until a definite reaction is obtained. Strong reactions are to be avoided, although some of the best results have been obtained following a strong reaction with active temperature rise and severe general reaction. A strong reaction indicates that the next dose should be reduced. There is no rule as to the amount of vaccine. If about four steadily increasing injections are given without reaction, the vaccine treatment is to be discarded. In some cases there is distinct reduction in the virulence or growth ability of the organisms without their disappearance.

Occasionally definite organisms are found and vaccine is prepared and given, but in spite of reactions no improvement occurs.
